## **Abstract**

In an equilibrium model of residential and workplace choice, we develop a measure of quality of life, incorporating commuting costs and wages based on place of work, to account for residential sorting on unobserved skills within metropolitan areas. Quality-of-life measures estimated for 2071 areas in the United States reveal that quality of life varies as much within metropolitan areas as between them and is highest in denser areas. Households bear significant commuting costs to enjoy the amenities of suburban areas, and are willing to pay significant amounts to live in areas with low crime and well-funded schools.

Keywords: Quality of life, commuting costs, compensating differentials, residential sorting, urban labor markets.

JEL Numbers: H4, J3, Q5, R1

# 1 Introduction

In a national market, households decide where to live both across and within metropolitan areas. This decision is based on many factors, including local costs of living, access to labor markets, and local amenities. While local costs and labor-market conditions can typically be measured, the value of local amenities cannot. However, when households are sufficiently mobile and homogeneous, it is possible to infer the value of amenities by determining how much households are willing to pay for them through higher housing costs or lower wages. Consequently, as was first explained by Rosen (1979), an area's overall quality of life (QOL) can be inferred by how expensive it is to live in relative to its local wage level. This methodology has been followed by Roback (1982), Beeson and Eberts (1989), Gyourko and Tracy (1991), Gabriel and Rosenthal (2004), Chen and Rosenthal (2008), and many others to measure overall quality of life and the value of specific amenities across metropolitan areas.

When measuring the value of amenities within metropolitan areas, most researchers since Oates (1969), have focused on differences in housing rents, assuming that all workers have access to the same labor-market opportunities, and that commuting-time differences among communities can be safely ignored or controlled for. Difficulties with this assumption are that not all residents in a metropolitan area work in the same place, and that wages can vary significantly within a metropolitan area due to wage gradients, which compensate for commuting costs (Muth 1969, Straszheim 1984, Zax 1994). Thus some households may be taking shorter commutes and receiving a lower wage, while others are commuting longer to get higher wages.

The one well-known study of quality of life at the sub-metropolitan level, Blomquist, Berger, and Hoehn (1988), deals with this problem by assuming that all workers live and work in the same county. They measure county-level quality of life according to county-level housing prices relative to county-level wage levels, as predicted by households' place of residence, with no controls for commuting time.<sup>1</sup>

---

<sup>1</sup>Hoehn, Berger, and Blomquist (1987) consider a monocentric-city model where rents depend on distance to the city center, although they assume that all workers receive the same wage. They do not account for commuting in their analysis.

The approach of treating every locality as an island may be appropriate when comparing metropolitan areas, across which commuting is generally rare. In fact, local commuting patterns are used to group smaller areas, like counties, together and define them as metropolitan areas. Within metropolitan areas, this “island” treatment seems inappropriate for the same reason: for example, over 26 percent of commuters cross county lines.<sup>2</sup> Real estate agents often advise buyers to “drive until you qualify,” meaning that they should commute long enough from their work, so that prices fall to the point that they can afford a house with the characteristics and amenities that they desire. Indeed, many households may choose not to live in central cities, closer to work, because those areas offer inadequate schools, safety, or other amenities. In pursuit of the amenities they desire, workers may choose either to take long commutes, or to take lower-paying jobs with shorter commutes. The other issue with using “island” measures is that individuals may sort residentially by their skills, not all of which are observed. As a result, an area with highly-skilled workers may be inferred to have a low quality of life because it appears to offer workers a wage premium as compensation for disamenities, when in fact it has to do with unobservable skills.

In order to construct sub-metropolitan measures of quality of life, we deal with these local labor-market issues by explicitly accounting for commuting costs, both in time and money, and using wage premia based on place of work, rather than place of residence. This wage measure is more theoretically appropriate as workers wages depend causally on where they work, not on where they live. Furthermore, Fu and Ross (2010) provide evidence that workers’ unobserved skills are related to where they live, but not to where they work, where wage premia are determined by urban agglomeration economies. Constructing wage measures in this way leads to smoother variation of wages across metropolitan areas, rather than the discontinuous variation that would result from residence wage measures (due to sorting).

In section 2, we expand the conventional model of household location used to infer quality of life to allow for workers to commute between areas of residence and of work. Section 2.2 establishes that workers may implicitly pay for valuable amenities either through higher housing

---

<sup>2</sup>Authors’ own calculation from County-to-County Worker Flow Data, 2000 Census of Population and Housing.

costs or commuting costs, both of which are often termed “urban costs.” This model is made operational by calibrating it in section 2.3 to household characteristics, and tying in estimates of housing-cost, wage, and commuting-cost differences across areas in the United States, presented in section 3. In particular, section 3.2 describes how housing costs differ due to location rather than due to housing composition, and how the two are generally unrelated. Section 3.3 underscores how workplace-based measures of wages better describe wage opportunities than residence-based measures, which appear to strongly reflect unobserved skills, and how it appears that residential sorting within metropolitan areas is greater than across them. Section 3.4 explains our estimates of commuting costs, and how they tend to be higher in places with lower housing costs, conditioning on wage opportunities.

In section 4 we present the first economic sub-metropolitan measures of quality of life for the entire United States, mapping it over the country, and zooming in on several prominent metropolitan areas. Often, we are able to calculate these measures within county, and we present specific measures for neighborhoods in Manhattan and San Francisco, as well as within other metropolitan areas. We find that commuting costs make several of the largest metropolitan areas appear more attractive, particularly in the suburbs. Although the metropolitan-level measures of quality of life are generally consistent with those in Albouy (2008), there is roughly as much variation in quality of life within metropolitan areas as across them. For instance, the metro areas of New York and Detroit offer some of the most and least amenable areas in the country. The hedonic relationship between the overall quality-of-life measure and specific amenities is explored in section 5, which presents tentative evidence that households will pay dearly to live in areas with low crime and well-funded schools, as well as areas with more bars and restaurants. We conclude by considering the advances and shortcomings of this piece, including issues of residential sorting according to preferences for amenities.

## 2 A Model of Residential Choice with Commuting

### 2.1 Household Preferences and Constraints

This model incorporates commuting costs into the canonical model of Rosen (1979) and Roback (1982), expanded by Albouy (2008) to incorporate federal taxes, non-housing costs, and non-labor income. Households are homogeneous and consume a tradeable good,  $x$ , with price normalized to one, a non-traded “home” good,  $y$ , with price  $p$ , time spent on leisure,  $l$ , time spent commuting,  $f$ , and a vector of amenities,  $\mathbf{Z}$ , which are aggregated into a single quality-of-life index,  $Q = \tilde{Q}(\mathbf{Z})$ . Household preferences are then modeled by a utility function,  $U(x, y, l, f; Q)$ , which is quasi-concave and increasing in  $x$ ,  $y$ ,  $l$ ,  $f$ , and  $Q$ , meaning that preferences for consumption goods and amenities are weakly separable. Households are fully mobile and choose their place of residence,  $j$ , which differ in local prices,  $p^j$ , and local amenities,  $Q^j$ . Households also choose their place of work,  $k$ , which differ in the local wage,  $w^k$ , where they may work  $h$  hours. Commuting to work takes time  $f^{jk}$ , and is assumed to have a proportional monetary cost,  $c \cdot f^{jk}$ , where  $c \geq 0$  is a constant. Households receive income from wages,  $w^k h$ , plus non-labor income,  $I$ , from a fully-diversified share of land and capital in the economy, but pay federal taxes  $\tau(w^j h + I)$ , which are rebated lump-sum back in  $I$ . State taxes and tax benefits to owner-occupied housing are modeled in Appendix C.

The household budget constraint is then

$$x + p^j y + c f^{jk} \leq w^j h + I - \tau(w^j h + I), \quad (1)$$

while the time constraint must satisfy

$$h + l + f^{jk} \leq 1, \quad (2)$$

and the time endowment is normalized to one. These two constraints may be used to construct the following expenditure function, defined precisely as the the after-tax net expenditure necessary for

a household to obtain utility  $u$ , given their circumstances

$$e(p^j, w^k, f^{jk}; Q^j) = \min_{x,y,h,l} \{x + p^j y - w^j h - I + cf^{jk} + \tau(w^j h + I) : U(x, y, l, f^{jk}; Q^j) \geq u, h + l + f^{jk} \leq 1\}, \quad (3)$$

which is increasing in  $p^j$  and  $f^{jk}$ , and decreasing in  $w^k$  and  $Q^j$ .

## 2.2 Equilibrium in Place of Residence and Work

Households are fully mobile so no combination of place of work and place of residence that is undertaken can offer a lower utility than any other. All existing combinations  $(j, k)$  must offer the same level of utility,  $u$ , meaning that in equilibrium, no households need to be paid an additional amount to take their choices. This allows us to express the equilibrium condition as

$$e(p^j, w^k, f^{jk}; Q^j) = 0, \quad (4)$$

for all  $j$  and  $k$  combinations that are observed. Therefore, places with high prices need to compensate their workers with good amenities or with short commutes to high-paying jobs.

To better interpret the model we implicitly differentiate condition (4), assuming that it is continuously differentiable in a neighborhood of its arguments, around an observed equilibrium. In choosing a place of residence, we should then see the following approximation hold:

$$\frac{\partial e}{\partial p} dp^j + \frac{\partial e}{\partial f} df^j + \frac{\partial e}{\partial Q} dQ^j = 0. \quad (5)$$

With some abuse of notation,  $df^j$  is the change in commuting time due to varying residences. This expression provides a generalization of an urban housing-cost, or rent, gradient. The urban-wage

gradient is expressed by varying the place of work, requiring that

$$\frac{\partial e}{\partial w} dw^k + \frac{\partial e}{\partial f} df^k = 0. \quad (6)$$

Here  $df^k$  is the change in commuting time by varying workplaces. Note that these are an approximation around a specific value, which we assume to be the national average.

Adding the rent and wage gradients (5) and (6) together,  $-\frac{\partial e}{\partial p} dQ^j = \frac{\partial e}{\partial p} dp^j + \frac{\partial e}{\partial w} dw^k + \frac{\partial e}{\partial f} (df^j + df^k)$ , and applying the envelope theorem (e.g. Shepard's Lemma), the marginal willingness-to-pay for local quality of life is

$$p_Q dQ^j = \bar{y} \cdot dp^j - (1 - \tau') \bar{h} \cdot dw^k + [c + (1 - \tau') \bar{w} - \alpha] df^{jk}, \quad (7)$$

where  $p_Q \equiv \partial e / \partial p = (\partial U / \partial Q) / (\partial U / \partial x)$  is the marginal valuation of  $Q$ ,  $df^{jk} \equiv df^j + df^k$  is the total difference in time spent commuting, and  $\alpha \equiv (\partial U / \partial f) / (\partial U / \partial x)$  is the marginal value of commuting, expressed in money.<sup>3</sup> The first two terms on the right express the classic formulation that households will pay higher rent,  $\bar{y} \cdot dp^j$ , or receive lower, net-of-tax earnings,  $(1 - \tau') \bar{h} \cdot dw^k$ , to enjoy a higher quality of life. The last term expresses that they may also be willing to bear higher commuting costs,  $[c + (1 - \tau') \bar{w} - \alpha] df^{jk}$ , which are the sum of material costs and time costs, net of the leisure value of commuting. When the expression is rearranged to have wages on the left-hand side, it says that households will pay higher urban costs,  $\bar{y} \cdot dp^j + [c + (1 - \tau') \bar{w} - \alpha] df^{jk}$ , given by higher rents and longer commutes, to access urban amenities or employment opportunities,  $p_Q dQ^j + (1 - \tau') \bar{h} \cdot dw^k$ .<sup>4</sup>

---

<sup>3</sup>Note that since  $Q$  does not have any natural units, neither  $p_Q$  nor  $dQ^j$  have operational meaning, although their product,  $p_Q dQ^j$ , does as the marginal willingness-to-pay to enjoy the amenities in location  $j$ .

<sup>4</sup>Timothy and Wheaton (2001) consider the situation when wages,  $w^k$ , are exogenous. Then, only in knife-edge cases will households commute to more than one work place from the same place of residence. With endogenous wages, wages may adjust to make this less rare. Moreover, in a more realistic model, workers may vary in their transportation costs, or receive idiosyncratic wage offers from different locations, each with mean  $w^k$ , which could cause workers from the same residences to commute to a large variety of workplaces.

## 2.3 Applying and Calibrating the Model

For the sake of application, we log-linearize (7) by dividing through by average income  $\bar{m}$ , and rearrange it to express differences in terms of log differentials  $\hat{p}^j \equiv dp^j/\bar{p}$ ,  $\hat{w}^k \equiv dw^k/\bar{w}$ ,  $\hat{f}^{jk} \equiv df^{jk}/\bar{f}$ , which are estimated from the data. The marginal willingness-to-pay for local amenities, expressed as a fraction of income,  $\hat{Q} \equiv p_Q dQ^j/\bar{m}$ , is then

$$\hat{Q}^j = s_y \hat{p}^j - (1 - \tau') s_w \hat{w}^k + \underbrace{\left\{ s_c + \left[ (1 - \tau') s_w \frac{\bar{f}}{\bar{h}} + \alpha \frac{\bar{f}}{\bar{m}} \right] \right\}}_{\hat{c}^{jk}} \hat{f}^{jk}, \quad (8)$$

where  $s_y = \bar{p}\bar{y}/\bar{m}$  is the expenditure share for home goods,  $s_w \equiv \bar{w}\bar{h}/\bar{m}$  is the income share from labor,  $s_c \equiv c\bar{f}/\bar{m}$  is share of income spent on commuting, and  $\bar{f}/\bar{h}$  is the ratio of time spent commuting to time spent working. The total associated differences in commuting costs,  $\hat{c}^{jk}$ , is termed the commuting-cost differential.

Following Albouy (2008), the parameters unrelated to commuting are calibrated as  $s_w = 0.75$ ,  $s_y = 0.33$ , and  $\tau' = 0.35$ . This allows for the fact that, across households, about 25 percent of income is derived from non-labor sources. Furthermore, the price of goods other than housing is strongly related to the costs of local housing, leading us to put a higher weight on housing costs than the literal expenditure share on housing, which is closer to 0.22. Marginal tax rates are based on average income tax rates as well as a portion of payroll tax rates, and some amount for state taxes, insofar as wages vary within states.<sup>5</sup> We take into account that transportation costs are endogenous to the mode of transportation. Following the SIPP<sup>6</sup>, we set  $s_c = 0.049$ , while for transit riders, we use  $s_c = 0.033$ , and for walkers,  $s_c = 0.0$ .

Based on information from the SIPP and the National Highway Summary of Travel Trends, the fraction of time spent commuting is set at  $\bar{f}/\bar{h} = 0.10$ . The average worker in 2000 worked 1822 hours (U.S. Census) and spent 184 hours commuting, which is the product of 418 one-way trips to and from work averaging 26.4 minutes each way. We have decided to treat  $\alpha = 0$  based

---

<sup>5</sup>See Appendix C.2 for full details of state tax calibration.

<sup>6</sup>Calculations from the U.S. Department of Transportation, Bureau of Transportation Statistics using data from the *Survey of Income and Program Participation* 2001 Panel

on the assumption that the marginal value of time spent commuting is equal to the marginal value of time spent working. This is consistent with recent evidence from Small et al. (2005) based on stated and revealed preference, as well as subjective well-being data from Kahneman and Krueger (2006), whereby individuals exhibit as low an affect while commuting as while working. Alternate values of  $\alpha$ , which could be negative or positive, could easily be accounted for. Overall, the linear nature of (8) makes it very easy to see how quality-of-life measures may change with alternate calibrations, as well as how the differential measures described below are used to construct our chosen estimates.

## 3 Wage, Housing-Cost, and Commuting-Cost Differentials

### 3.1 Units of Geography

Wage, housing-cost, and commuting-cost differentials are calculated using data from the 5 percent sample of the U.S. Census from the Integrated Public Use Microdata Series (IPUMS), by Ruggles et al. (2004). The public-use files only allow the residence of households to be identified down to the level of geography known as the Public Use Microdata Area (PUMA), of which there are 2071, all with over 100,000 inhabitants. While the geography of PUMAs is not always intuitive they often correspond to counties or groups of counties, and in denser areas, to sub-county areas that map to identifiable neighborhoods or municipalities. For example, in Washtenaw County, MI, one PUMA corresponds to the city of Ann Arbor while another refers to all areas in Washtenaw County other than the city. In the borough of Manhattan, also known as New York County, NY, ten areas are identified which correspond to sub-boroughs, such as the Upper East Side and Central Harlem. For place of work, the public-use files only allow identification at the Place of Work Public Use Microdata Area (PWPUMA), which number 1240, and encompass one or more standard PUMAs.

Areas are classified into metropolitan areas by the Office of Management and Budget (1999). Using these 1999 definitions there are 276 Metropolitan Statistical Areas (MSAs). Some large MSAs are categorized instead as Consolidated MSAs (CMSAs) which are in turn made up of 2

or more Primary MSAs (PMSAs). There are 19 CMSAs and 55 PMSAs. Within each MSA, the largest place and, sometimes, other places are designated as “central cities,” which together contain 29 percent of the US population.<sup>7</sup> We labeled non-central city areas within MSAs as “suburban,” and areas completely outside of MSAs as “non-metropolitan.” PUMAs can usually be assigned uniquely to different MSAs, but in cases where they overlap MSA (or county) boundaries, the observations are subdivided and given a fractional weight according to the proportion of the population that resides in each area. We also classified areas according to the average residential population density, which was calculated at the census-tract level and averaged by population.

Panel 1 of Table 1 presents means of the estimated differentials and related statistics for central city, suburban, and non-metropolitan areas. Panel 2 presents this information summarized by the location’s average density. Panel 3 presents the standard deviations of the differentials across the United States, and decomposes the variance within and across metropolitan areas (grouping non-metropolitan areas of each state together and treating them as distinct MSAs). In Table 2, these statistics are presented for PUMAs in two of the best-known counties in the United States: New York County, NY, and San Francisco County, CA, which is contiguous with the City.

### **3.2 Housing Costs due to Location and Composition**

Both housing values and gross rents, including utility costs, are used to calculate a flow value of housing costs. Following previous studies, imputed rents are converted from housing values using a discount rate of 7.85 percent (Peiser and Smith 1985), with utility costs added, to make the imputed rents comparable to gross rents. To avoid measurement error from imperfect recall or rent control, the sample includes only units that were acquired in the last ten years.<sup>8</sup> Log housing costs are regressed on place-of-residence indicators,  $\mu_p^j$ , and controls for housing composition, denoted

---

<sup>7</sup>For instance, all of New York City, Bridgeport, Newark, and New Haven are deemed central city, but none of Long Island is. The cities of San Francisco, Oakland, San Jose, Berkeley, and Richmond are all central, but Fremont, Hayward, Union City, and all of Marin and San Mateo counties are not.

<sup>8</sup>We combined rent and imputed-rent measures to avoid potential problems created by differences in home-ownership by location. For instance, the difference between rented and owned units in Manhattan, where 80 percent of housing units are rented, may differ significantly from the difference in King William Co., VA, where 13 percent are rented.

$X_{pi}^j$  – i.e., size, rooms, acreage, commercial use, kitchen and plumbing facilities, type and age of building, and residents per room – all of which are fully interacted with renter status. The resulting regression equation is

$$\ln p_i^j = X_{pi}^j \beta_p + \mu_p^j + \varepsilon_{pi}^j, \quad (9)$$

where estimates of  $\mu_p^j$  are the housing-cost differentials,  $\hat{p}^j$ , for location  $j$ . Remaining differences in mean housing costs,  $\overline{\ln p^j} - \mu_p = \bar{X}_p^j \beta^j$ , are attributed to mean differences in observable housing composition across areas,  $\bar{X}_p^j$ , which relates both to the quantity and quality of housing consumed.

Proper identification of housing-cost differentials requires that mean differences in unobservable housing characteristics across areas are zero. This is of concern, since housing units may vary considerably across areas. For example, two-bedroom apartments in the suburbs may be more spacious than those in the central city and may be considerably better maintained in desirable areas than in less desirable ones. An overstated housing-cost differential will bias quality-of-life estimates upwards, and thus one must bear in mind that quality of life may also capture differences in unobserved housing quality.<sup>9</sup> Another issue is that the Census does not provide information about what units are rent controlled, which is of particular concern in a few prominent cities. Using the work of Pollakowski (2003), we imputed what housing costs would be in the absence of rent control, causing them to be slightly higher in “core” Manhattan and San Francisco.<sup>10</sup>

In addition to constructing housing-cost differentials as described above, we use the observable characteristics of housing alone to predict housing-cost due to composition. In other words, this composition value is the value of housing predicted solely from  $X_{pi}^j$ , observable characteristics, without accounting for locational fixed effects.

In column 2 of Panel A of Table 1, we see that the housing-cost index is 2 log points higher

---

<sup>9</sup>For the homes of the very wealthy, this effect is mitigated by the fact that housing values are censored at \$1 Million. Furthermore, Malpezzi et. al. (1998) determine that housing-cost indices derived from the Census in this way perform as well or better than most other indices.

<sup>10</sup>Pollakowski estimates that in “core” Manhattan areas, the lower 6 neighborhoods, rent-controlled units would be 37 percent higher without rent control. Using a similar method with Census data, we determined that rent-controlled units in San Francisco would be 22 percent higher in the absence of rent control. To correct for this, we added the fraction of rent-controlled units in each PUMA times  $\ln(1 + a)$  to the housing cost index, where  $a$  is how much units would appreciate without rent control.

in suburban areas than in central cities, and 41 log points higher than non-metropolitan areas. However, as seen in Panel B, the highest housing costs are nonetheless in the densest areas. In column 3, we see that housing units in the suburbs and in areas with moderate densities have the highest value predicted by observable characteristics, while those in the central city and in high-density areas have the lowest value: the most straightforward explanation for this phenomenon is that units in denser, central areas are smaller.<sup>11</sup> In Manhattan, units in lower cost Harlem have a higher value than units in Midtown, Downtown, or the Upper East and West Sides.

Panel C provides evidence that while there is considerable variation in housing costs due to composition across areas, there are much greater differences in housing costs due to location. At the PUMA level, a greater fraction of housing-cost variability occurs across metro areas, than within them. The opposite is true of differences in composition, which are relatively small across metro areas.

### 3.3 Wage Levels by Workplace and Residence

Wage differentials,  $\hat{w}^k$ , are calculated from the logarithm of hourly wages from a sample of workers, ages 25 to 55, who worked at least 30 hours a week and 26 weeks a year. These differentials control for skill differences across workers to provide an analogue to the representative worker in the model. Log wages are regressed on place-of-work indicators,  $\mu_w^k$ , and controls for worker composition, or “skills,”  $X_{wi}^k$ , – i.e., education, experience, race, occupation, industry, and veteran, marital, and immigrant status – each interacted with gender. The regression equation is

$$\ln w_i^k = X_{wi}^k \beta + \mu_w^k + \varepsilon_{wi}^k. \quad (10)$$

Unlike the housing-cost differentials which are estimated by place of residence, the wage differentials for residents of location  $j$ ,  $\mu_w^j$ , must be constructed since wages are first estimated based

---

<sup>11</sup> As shown in Appendix Figure A1, the correlation between locational and compositional housing-cost measures is zero across PUMAs. However, when density is flexibly controlled for, a one-point increase in housing-cost predicts a 0.12 point increase in the value of housing composition.

on place of work. We construct these local wage measures by averaging  $\mu_w^k$ , according to the proportion of residents of  $j$  who work in each place  $k$ . This differential is interpreted as the measure of the wage opportunities available to residents of location  $j$ , when they are willing to pay the commuting costs estimated below, and is used in place of  $\hat{w}^k$  to estimate quality-of-life.

Identifying the wage differentials accurately requires that workers do not sort across workplaces according to their unobserved skills. Fu and Ross (2010) provide considerable evidence that wage levels estimated at the workplace are due to agglomeration economies, and not unobserved skill differences, as their strong relationship with employment density is not affected when place of residence is controlled for. They are well explained by commuting costs, as an equilibrium model of the wage gradient seen above predicts. While this provides evidence against workplace sorting, wage levels estimated using residence indicators, in an equation analogous to (9), are subject to residential sorting. Figure 1 graphs wage estimates by workplace against estimates by residence, showing that the former vary less than the latter. This is apparent in Table 2, where wages by residence vary remarkably in Manhattan; from 47 log points in the Upper West Side to only 3 log points in Washington Heights. The residence wage estimates are hard to interpret causally, since these locations are separated by only a short commute, and therefore should offer similar wage opportunities. However, this similarity is reflected in wages by workplace, which differ by only 4 log points. Overall, according to column 4 of Table 1, workplace wages for central city residents are as high as for suburban residents, are higher for residents of denser areas, and vary little within metropolitan areas relative to across them. Residential wage measures, in column 5, indicate wage opportunities are lower in central cities, contradicting most models of wage gradients.

The difference between workplace and residence-based wage measures is perhaps best interpreted as differences in unobserved skills, such as in the quality of human capital. This difference is illustrated in Figure 1 by the distance rightward from the diagonal to each PUMA's marker. It seems likely that workers with lower unobserved skills should live in the same areas as those with lower observed skills. This conforms to patterns seen in column 6 of Table 2: lower levels of both types of skills are seen in central cities, and in neighborhoods such as Harlem and Bayview; higher

skill levels of both kinds are found in the suburbs, and in neighborhoods such as the Upper East Side and North Beach. Across PUMAs, a one-point increase in wages due to unobserved skills predicts a 1.07-point increase in wages predicted by observable skills. Unlike the wage differentials by workplace and residence, wages due to differences in skills, observed or not, vary much more within metro areas than across them. This supports the view that residential sorting is more important within metro areas than across them, and that wage differences across metro areas are due to local productivity, such as from agglomeration, rather than from worker selection.

While the wage measures used here may be biased by sorting on unobserved ability, particularly across metropolitan areas, the available evidence suggests these effects are rather weak. For smaller geographic areas our workplace wage measures are certainly an improvement over residence-based wage measures for the reasons discussed above. An overstated wage differential for a location will bias its quality of life downwards. Thus, if residence-based wage levels are used instead of workplace wages, then areas with highly skilled residents will have their wage opportunities overestimated and their quality of life underestimated.

### 3.4 Commuting Costs

Commuting-cost differentials are estimated from commuting times reported in the Census and are based on a worker's place-of-residence. The same sample is used for wages, and the equation is estimated from the logarithm of commute time, with place-of-residence indicators,  $\mu_f^j$ , and controls,  $X_{fi}^j$  – i.e., number of children, children under 6, self employment, relationship to the household head, and all of the controls used in the wage equation – each interacted with gender. Thus, the regression equation is

$$\ln f_i^j = X_{fi}^j \beta_f + \mu_f^j + \varepsilon_{fi}^j.$$

Estimates of  $\mu_f^j$  are used as commuting-time-cost differentials,  $\hat{f}^j$ .

In addition to calculating differences in commuting time, we also account for differences in

mode to estimate the monetary costs of commuting. Using a linear probability model, we calculate demographically-adjusted probabilities of using each mode of transportation,  $\rho_l^j$ , for modes  $l$  – own car, carpool, public transportation, and other methods including walking and biking. The overall cost is then the weighted average of the mode costs multiplied by the time differential, plus the average deviation in average monetary costs, determined by transportation modes,

$$\sum_l \rho_l^j c_l \hat{f}^j + \sum_l (\rho_l^j - \bar{\rho}) c_l.$$

For most areas outside of New York City, the adjustments for transportation mode are minor.<sup>12</sup>

Column 7 in Tables 1 and 2 report differences in the full cost of commuting, the last term of (8), which is inferred primarily from differences in commuting time, listed in column 8. These costs are lower in central cities and non-metro areas than in the suburbs, although the variation is small economically. Within New York and San Francisco, downtown residents have the lowest observed costs. Commuting costs are generally lowest in medium-density areas, and at the PUMA level these costs vary about as much within metropolitan areas as across them.

Commuting costs are plotted relative to housing costs in Figure 2, each residualized from local wage levels. A one-point increase in commuting costs is associated with a 1.72 point reduction in housing costs. This negative relationship is consistent with models of rent gradients, although when interpreted strictly through equation (8) the calibration predicts the slope should be -3.0, when holding quality-of-life constant within the metro areas. In that case, a one-percent increase in housing costs should lower real income by three percent. This suggests that, within metro areas, residents may be commuting longer in order to obtain better amenities.

---

<sup>12</sup>In New York City and the municipalities of San Francisco, Boston, Philadelphia, and Chicago, the monetary costs of transit riders are assumed not to vary by travel time, as their transit agencies charge a flat fare to their riders.

## 4 Quality of Life across the United States

Local quality-of-life differentials are estimated at the PUMA level using the housing-cost, wage, and commuting-cost differentials discussed above with a calibrated version of (8)<sup>13</sup>. These quality-of-life estimates are mapped in Figure 3 for the continental United States, and in Figures 4A, 4B, 4C, and 4D for areas around San Francisco, New York, Detroit, and Atlanta. Quality-of-life differentials for these four MSAs, and for Honolulu, are presented in Table 3, according to different levels of geography<sup>14</sup>. Each level of geography is given its own ranking by type, so there are separate rankings for MSAs, counties, and PUMAs. A full list of quality-of-life differentials for 2071 PUMAs appears in Appendix Table A1<sup>15</sup>.

The highest quality-of-life PUMA in the United States is East Oahu/Waialae-Kahala, where households sacrifice the equivalent of 29 log points of real after-tax income (25 percent) relative to the national average to live there. This PUMA is inside the Honolulu MSA, which was already found to be the highest quality-of-life MSA in Albouy (2008). The second best quality of life is found in the “San Rafael/Sausalito/Mill Valley” PUMA, which is inside Marin County, which offers the best quality of life among counties. Marin is found inside the San Francisco-Oakland-San Jose (or SF Bay Area) CMSA with the second highest quality of life among MSAs.<sup>16</sup> Without factoring in commuting, the SF Bay Area would be behind Santa Barbara and Salinas (Monterey Co.) MSAs, which have lower commuting times. Four of the six PMSAs in the SF Bay Area, are ranked as the nicest metros after Honolulu, when CMSAs are disaggregated (see Figure 4A).

The worst quality of life is found in southwest Detroit City, the Chadsey/Condon/Vernor PUMA (see Figure 4C), where households are compensated with 22 log points (25 percent) of real after-

---

<sup>13</sup>The preferred PUMA estimates include adjustments for state taxes and housing deductions. Refer to Appendix C for details.

<sup>14</sup>PUMAs are the smallest geographic unit we can identify using the Public-Use data. Quality-of-life estimates for larger areas are calculated by appropriately weighting and aggregating PUMA level estimates according to population and boundaries.

<sup>15</sup>Full rankings for the other levels of geography are available upon request

<sup>16</sup>Blomquist et al. (1988) found Alameda County, which contains Oakland, to be one of the best and Marin County to be one of the worst counties in the SF Bay Area. Among other things, this is probably due to their use of wage levels based on residence rather than place of work. As explained in Albouy (2008), the SF Bay Area in general fared badly in their article as they did not take into account federal taxes and non-housing costs-of-living.

tax income to live there (seen in Table A1). Although the Detroit MSA does not offer a very high average quality of life, it still contains areas with high quality of life, like West Bloomfield/Birmingham, ranked 71st among PUMAs. Flint and Ann Arbor are two cities near Detroit that are considered part of the Detroit CMSA but these have very different levels of quality of life. Although both satellite cities have higher than average wage levels, the housing costs and commuting costs are very different, signalling that Ann Arbor has more desirable amenities than Flint. The low commuting costs in Ann Arbor suggest that workers commute within the town for work, where the comparatively higher commuting costs for Flint suggest that many workers commute there.

New York City is an especially interesting case as the high population and high population density provide many different PUMAs spread over a relatively small landmass. Manhattan has only 23 square miles of land mass and is split into 10 different PUMAs (see Figure 4B). Due to the proximity of these areas, it is clear that the entire island can be considered one labor market. However, there is still significant variation in quality of life among these areas, apparent mostly in urban-cost differences. It may seem surprising that quality of life can vary so much over such a small geographic area, especially the juxtaposition between neighboring areas like the Upper East and West Sides and Harlem, but these differences are generally well known among locals.

The greater New York metropolitan area offers some of the best locations, including amenable suburbs such as Port Washington, Great Neck, Oyster Bay, Glen Cove and Jericho in Long Island, as well as the Upper East Side in Manhattan. This is counterbalanced by some of the least amenable areas in Harlem, South Bronx, and South Newark. Once again, we see quality of life varying to a great degree within a metropolitan area.

The best quality-of-life counties in the Atlanta metropolitan area are the suburban counties, DeKalb and Cobb, located right outside of the central city boundary. There is substantial variation within counties at the PUMA level. As shown in Figure 4D, the central city area of Atlanta (part of Fulton County) contains both the highest quality-of-life PUMA in the Atlanta MSA, Buckhead, right next to the lowest quality-of-life PUMA in the region, Center Hill-West Lake. Within the

Atlanta metropolitan area we see once again that wages are more similar than housing costs (see Table 3) and it is the variation in housing cost that has a larger effect on the local quality of life measurement.

The four MSAs focused on here show that households find the highest quality-of-life within metropolitan areas, but mostly outside of the central city areas. Panel A of Table 1 shows that this pattern for quality of life (column 9) holds generally for the entire United States. These suburbs have higher commuting costs (column 7) and higher prices (column 2) while having similar wage levels (column 4) as central city areas. This similarity in wages makes perfect sense when you remember that it is the labor market and commuting patterns that lead areas to be tied together and defined as metropolitan areas. Panel B also shows that denser areas are generally more amenable as well. Panel C shows that at the PUMA level within MSAs, there appears to be roughly the same amount of variation in quality of life as there is across MSAs, with a standard deviation in quality-of-life values equal to almost 5 percent of gross income. This is remarkable, since fewer amenities can vary within metro areas as opposed to across them<sup>17</sup>.

Several interesting trends emerge from the sub-metropolitan quality-of-life estimates. The quality of life in metro areas is generally found to be higher than in non-metro areas with the inclusion of commuting costs. Households put up with these higher costs to access the better jobs and amenities these areas generally offer. While both wages and housing costs vary less within MSAs than they do across MSAs, these examples match the general trend that within an MSA, wages vary less than housing costs do. This makes sense with a story of local labor markets that are larger than neighborhoods. When households move to New York for a job, they decide where to live according to the commute and amenity differences between the surrounding areas. The choice is not between living and working on the Upper East Side *or* living and working in East Harlem.

---

<sup>17</sup>For example, weather may not vary much within a metro area but certainly will across metro areas

## 5 Inferred Valuation of Specific Amenities

Based on hedonic theory, the quality-of-life values may be used to estimate how much value households put on particular amenities from a second-step regression,

$$\hat{Q}^j = \sum_k \pi_k^Q Z_k^j + \varepsilon^{Qj}, \quad (11)$$

where  $\pi_k = -(\partial E / \partial Q) (\partial \tilde{Q} / \partial Z_k) / \bar{m}$  measures the fraction of gross income a household is willing to pay for one more unit of amenity  $k$ . Multiplying this coefficient by average gross household income (\$68,000 in 2000) produces the dollar value. The residual  $\varepsilon^{Qj}$  results from measurement error, unobserved amenities, mis-specification, and unobserved differences in housing quality and worker skills. The separate contribution of wage, housing-cost, and commuting-cost effects are presented from regressions:

$$\hat{w}^j = \sum_k Z_k^j \pi_k^w + \varepsilon^{wj}, \quad \hat{p}^j = \sum_k Z_k^j \pi_k^p + \varepsilon^{pj}, \quad \hat{c}^j = \sum_k Z_k^j \pi_k^c + \varepsilon^{cj}, \quad (12)$$

where the model implies that  $\pi_k^Q = s_y \pi_k^p - (1 - \tau') s_w \pi_k^w + \pi_k^c$ .

Inferring specific amenity values with cross-sectional data faces many potential pitfalls. There is a high degree of collinearity between the amenity variables, making it difficult to obtain precise estimates for a reasonably large set of variables. Unmeasured amenities may contribute to omitted variable biases. Furthermore, artificial amenities may be highly endogenous, subjecting their estimated values to additional skepticism. Yet, oftentimes there is no other recourse, due to the unavailability of natural experiments and confounding factors in the dynamics of urban price and wage changes over time.

Table 4 reports the coefficient estimates from the amenity regressions<sup>18</sup>. The results that households value mild winters, mild summers, sunshine, and coastal proximity were already discernible from cross-metro estimates in Albouy (2008). Yet, those regressions do not provide evidence that

---

<sup>18</sup>A detailed description of the amenity data can be found in Appendix B

households are willing to pay to avoid crime, measured through the murder rate. Although we were only able to find nationally representative crime rates at the county level, which is still far too aggregated, the regressions associate an increase in the murder rate from 10 to 20 per 100,000 residents, the difference between Los Angeles and Philadelphia, with a reduction in willingness to pay of 1.7 percent of income, or \$1,150 per household. While substantial, this estimate is smaller than valuations of crime in Bishop and Murphy (2011), based on more geographically fine data for the SF Bay Area.

The estimates also reveal a high willingness to pay for school funding even if those require higher local taxes, which are not controlled for: an increase in funding of \$1,000 per student increases the willingness to pay of households 0.72 percent of income or \$490. Each household has on average 0.90 children, making it appear that school funding likely has a high return. Although it is problematic to interpret this result causally, these estimates are in the same order of magnitude as Black (1999), Bayer, Ferreira and McMillan (2007) and Caetano (2010), who find a very high willingness to pay for schools with better test scores. This could reflect that new home-buyers plan to use schooling services more than typical resident-taxpayers, or that the political process generally leads to sub-optimally funded public schools.

One advantage of having sub-metropolitan measures is that it allows us to consider variation within as well as across metropolitan areas. This is done here by adding MSA indicators, or “fixed effects,” to the regression equation, producing the results in column 5. This greatly reduces the identifying variation for a number of amenity variables, particularly for climate and geography, but helps to check the validity of the estimates for amenity variables that do vary within metropolitan areas. Indeed, a concern could be that valuation estimates are driven by differences in unobserved amenities or unobserved skill differences across metropolitan areas. Not surprisingly, the valuations for sunshine and coastal proximity become statistically indistinguishable from zero. On the other hand, valuations for school funding, safety from crime, and local bars and restaurants (which vary much more within metro areas) remain significant. Interestingly, we find similar, and arguably

larger valuations to avoid extreme temperatures and live on land with a greater slope.<sup>19</sup>

## 6 Conclusion

The inclusion of commuting costs into the canonical Rosen-Roback model of quality of life is quite natural, as standard urban economic models emphasize commuting as much as rents, when considering the costs of living and working in an urban area. Indeed, conditioning on wage opportunities we find that commuting and housing costs are negatively related.

Within metropolitan areas, there is also the additional problem that households may be sorting across neighborhoods according to unobserved skills, although this appears to be addressed fairly well by using wage levels based upon place of work, rather than residence. We find interesting evidence that there appears to be more skill sorting within metropolitan areas, as opposed to across them. Perhaps this is because local labor markets provide a centripetal force holding heterogeneous individuals together, who would otherwise choose to live in different areas that are far apart. Whatever the case, using workplace wages prevents areas such as Harlem from being seen as offering low wage opportunities, and thus overestimating its quality of life, rather than as being an area with lower-skilled workers.

Modeling these amendments, our nation-wide quality-of-life estimates provide some interesting comparisons across disparate parts of the United States, from rural areas on the plains, to cities on the coasts. We find as much variation in quality-of-life within metropolitan areas as we do across them. In particular, the highest amenity areas are generally found in denser suburbs, while low-density rural areas are the least amenable: these conclusions are only clear when commuting and residential selection are controlled for. Furthermore, the geographic detail of the data – the best available nationwide for public use – makes it easier to identify how much households value location-specific amenities, providing cross-sectional evidence, both within and across metropolitan areas, that households put great value on safety, schools, and leisure amenities, as well as mild

---

<sup>19</sup>Note that the data for these variables is arguably of higher quality than for the others.

climates and scenic geography.

Perhaps the greatest issue not addressed here is how households sort according to their tastes for local goods. For example, the strong willingness-to-pay for suburbs with good schools may reflect the fact that those with the strongest demand for housing tend to be parents. Further research is certainly warranted in measuring the willingness to pay for different amenities across households, according to both observed and unobserved traits. Nonetheless, the importance of preference heterogeneity should not be overstated: we imagine that most Americans would prefer to live on the beaches of Hawaii, than in the crime-ridden areas of Detroit, if they were guaranteed the same level of private consumption in either locale. We hope that our attempts at incorporating commuting costs and workplace wage-measures helps to integrate urban economic models of rent and wage gradients with those used to value household amenities.

Wage, housing price, and commuting data are taken from the U.S. Census 2000 IPUMS for 2071 Public-Use Microdata Areas (PUMAs). Differentials are relative to the national average. Housing-cost differentials are based on the average logarithm of gross rents or housing prices plus utilities, with the cost-index determined by the indicator for what PUMA it is located in, and the composition index by the predicted value based on other observable housing characteristics. Wage differentials are based on the average logarithm of hourly wages for full-time workers ages 25 to 55, with the "By workplace" differential estimated off of work-place indicators, averaged over resident workers, the "By Residence" estimated off of residential indicators, and the "Composition" index by the wage predicted by observable characteristics. Commuting-cost differentials for workers are estimated from monetary-cost and time-cost differentials explained in the text, the latter based on time to work. The adjusted quality-of-life index is estimated from the housing-cost, workplace-wage, and commuting-cost indices, according to equation (8), as calibrated in the text, while the simple index is estimated from the housing-cost and residence-wage indices, only. In Panel C, non-metropolitan areas of each state are treated like a distinct metropolitan area, although the results do not change substantially if they are excluded. See text for greater detail.

Differentials are relative to the national average. The sub-county measures are for Public-Use Microdata Areas, each containing over 100,000 inhabitants. Area names for the PUMAs here are based on sub-borough and planning area names from the Census. To offset bias due to rent control, the fraction of units that are controlled was multiplied by  $\ln(1.37)$  in the six lower sub-boroughs of Manhattan and by  $\ln(1.19)$  in San Francisco. Quality-of-Life Rankings are out of 2071 PUMAs. See Table 1 and Figures 3A and 3B for more.

Units of geography are MSA, PMSA, County, and PUMA. MSAs that contain several PMSAs, are also called "CMSAs". The PMSA ranking also includes MSAs that do not contain PMSAs. Counties may be larger, equal to, or smaller than PUMAs. Only some sub-geographies are shown; the rest are contained in Appendix Table A1. The rankings in column 6 are different for each type of geography, and are indented at the same levels as the names. There are 3081 counties, 2071 PUMAs, 373 PMSA or PMSA-equivalents, and 327 MSAs or MSA-equivalents, in the sample. See Table 1 for greater detail.

TABLE 4: HEDONIC ESTIMATES OF THE VALUE OF INDIVIDUAL AMENITIES

## A Wage, Housing-Cost, and Commuting-Cost Data and Estimation

United States Census data from the 2000 Integrated Public-Use Microdata Series (IPUMS), from Ruggles et al. (2004), are used to calculate wage, housing-price, and commuting-time differentials. The wage differentials are calculated for workers ages 25 to 55, who report working at least 30 hours a week, 26 weeks a year. The wage differentials are found by regressing log hourly wages on individual covariates and indicators for which PWPUMA a worker works in, using the coefficients on these indicators. The covariates consist of

- 12 indicators of educational attainment;
- a quartic in potential experience, and potential experience interacted with years of education;
- 9 indicators of industry at the one-digit level (1950 classification);
- 9 indicators of occupation at the one-digit level (1950 classification);
- 4 indicators of marital status (married, divorced, widowed, separated);
- an indicator for veteran status, and veteran status interacted with age;
- 5 indicators of minority status (Black, Hispanic, Asian, Native American, and other);
- an indicator of immigrant status, years since immigration, and immigrant status interacted with black, Hispanic, Asian, and other;
- 2 indicators for English proficiency (none or poor).

All covariates are interacted with gender.

This regression is first run using census-person weights. From the regressions a predicted wage is calculated using individual characteristics alone, controlling for PWPUMA, to form a new weight equal to the predicted wage times the census-person weight. These new income-adjusted weights are used so workers can be weighted by their income share. The new weights are then used in a second regression, which is used to calculate the PUMA wage differentials from the PWPUMA indicator variables. In practice, this weighting procedure has only a small effect on the estimated wage differentials.

Housing-price differentials are calculated using the logarithm of reported gross rents and housing values. Only housing units moved into within the last 10 years are included in the sample to ensure that the price data are fairly accurate. The differential housing price of an PUMA is calculated in a manner similar to wages, using a regression of the actual or imputed rent on a set of covariates at the unit level. The covariates for the adjusted differential are

- 9 indicators of building size;

- 9 indicators for the number of rooms, 5 indicators for the number of bedrooms, number of rooms interacted with number of bedrooms, and the number of household members per room;
- 2 indicators for lot size;
- 7 indicators for when the building was built;
- 2 indicators for complete plumbing and kitchen facilities;
- an indicator for commercial use;
- an indicator for condominium status (owned units only).

A regression of housing values on housing characteristics and PUMA indicator variables is first run using only owner-occupied units, weighting by census-housing weights. A new value-adjusted weight is calculated by multiplying the census-housing weights by the predicted value from this first regression using housing characteristics alone, controlling for PUMA. A second regression is run using these new weights for all units, rented and owner-occupied, on the housing characteristics fully interacted with tenure, along with the PUMA indicators, which are not interacted. The house-price differentials are taken from the PUMA indicator variables in this second regression. As with the wage differentials, this adjusted weighting method has only a small impact on the measured price differentials.

Commuting Time differentials are calculated using in a similar manner. The sample restriction is the same as that used for the wage differential calculation, except that in addition, individuals with missing commute time are dropped from the sample. The individual covariates for the commute time regression contain the same covariates used in the wage regression, including these additional variables:

- 7 indicators for number of children;
- 7 indicators for number of children under the age of 6;
- 1 indicator for self-employment status;
- 6 indicators for the relationship to the household head (spouse, child, sibling, etc.).

The commute time regression is run using the same income adjusted weights as the wage regression to calculate PUMA commute-time differentials from the coefficients of the PUMA indicator variables. As before, this adjusted weighting method has a only a small impact on the measured commute-time differentials.

Commuting mode proportions are estimated for all PUMAs using a linear probability model with US Census Data. Mode of transportation to work is split into four broad categories; travel to work by own automobile, carpool, public transportation, and a no-cost method. The public transportation category includes bus, streetcar, rail, subway, and ferry. The no-cost methods are working from home, walking, biking, and other. Binary variables for these four categories are separately regressed on 2071 PUMA dummies and the following variables interacted with gender:

- age ;
- 12 indicators for educational attainment;
- 4 indicators of marital status (married, divorced, widowed separated);
- 7 indicators for number of children;

The resulting estimated probabilities fall between 0 and 1 except for 7 PUMAs, all in Texas, where the estimated probability of public transportation was slightly negative (the smallest value is -.002). These values were set to zero and the other three categories were scaled up proportionally so that for every PUMA the proportions of the four transportation modes were non-negative and summed to one. To create the share of income spent on commuting by PUMA, these estimated proportions for transportation mode by PUMA were used with values of the median share of income spent on commuting reported by the Bureau of Transportation Statistics based on SIPP data. This value is 4.9% for car users and 3.3% for public transportation users. To calculate costs of carpooling, the national average value of income spent on commuting by automobile is divided by the national average number of carpoolers conditional on carpooling. This assumes that all members of a carpool share the cost of commuting equally. The direct cost of commuting for working from home, walking, biking, and other is assumed to be zero.

## B Amenity Data

**Heating and cooling degree days** are measurements used to estimate amounts of energy required to maintain comfortable indoor temperature levels. Daily values are computed from each day's mean temperature ( $\frac{max+min}{2}$ ). Daily heating degree day values are equal to  $\max\{0, 65 - mean temp\}$  and daily cooling degree day values are  $\max\{0, mean temp - 65\}$ . Annual degree days are the sum of daily degree day values over the year. The data here refer to averages from 1970 to 2000 (National Climactic Data Center 2008).

**Sunshine** is measured as average percentage of possible. This data set contains information on sunshine as percent of possible sunshine received, by month, for 156 stations in the contiguous United States. The total time that sunshine reaches the surface of the earth is expressed as the percentage of the maximum amount possible from sunrise to sunset with clear sky conditions. (National Climactic Data Center 2008)

**Inverse Distance to Coast** is equal to one over the distance in miles from the population-weighted centroid of the PUMA to the nearest coastline of an Ocean or Great Lake. Coded by author.

**Average Slope of Land** measures the average slope of the land according to census tract data. We used high-resolution elevation data from the Global 30 Arc Second Elevation Data (GTOPO30) digital elevation model (DEM) available from the United States Geological Survey. These data are set on a high resolution grid of roughly 11 kilometers. We mapped the girded elevation data to our PUMA geography averaging the value of all grid points falling within the boundary of each geography. The slope is computed using the average maximum technique, where the slope at each grid point is the maximum rate of change of

elevation from that grid point to its eight neighbors. Due to the high resolution of the data, all geographic units had at least one grid falling inside its boundary. (United States Geological Survey)

**Murder Rate** is the average number of murders per 1,000 inhabitants. It is reported at the county level. (FBI 2000 Uniform Crime Reports)

**Bars and restaurants** data are the number of establishments classified as eating and drinking places, NAICS 722. (County Business Patterns 2000).

**School Revenues per Student** data is at the county level and applies to public schools. (2000 Common Core)

## C Additional Tax Details

### C.1 Tax Advantages for Housing and Local Taxes

Tax advantages for owner-occupied housing are modeled by allowing households to deduct a fraction  $\delta \in [0, 1]$  of home-good expenditures,  $py$ , from their federal income taxes, so that taxes paid are  $\tau(m^j - \delta p^j y)$ .  $\delta$  should be less than 1 as these advantages do not apply to certain taxes (e.g. payroll) or to certain home goods, such as haircuts or restaurant meals. Nor are these advantages available to all workers: many renters and home-owners do not itemize deductions for mortgage interest or local taxes. Ignoring for now commuting and leisure, incorporating the home-good deduction into the income tax,  $\tau(m - \delta py)$ , changes the expenditure function to  $e(p, u, \tau(m - \delta py); Q) \equiv \min_{x,y} \{x + py + \tau(m - \delta py) : U(x, y; Q) \geq u\}$ . Differentiating the mobility condition and using the envelope theorem yields the log-linearized mobility condition

$$\hat{Q}^j = (1 - \delta\tau') s_y \hat{p}^j - (1 - \tau') s_w \hat{w}^j \quad (\text{A.1})$$

which replaces (8). As calibrated in Albouy (2008), this reduces the weight on  $\hat{p}^j$  from 0.36 to 0.33.

### C.2 Including State Tax Differences

Differences in within-state tax burdens are worth considering as wages and prices can often vary significantly within a state, while state services largely do not. State-tax differentials are computed by multiplying state tax and deduction rates by the wage and price differentials within state

$$d\tau_S^j/m = \tau'_S [s_w(\hat{w}^j - \hat{w}^S) - \delta_S s_y(\hat{p}^j - \hat{p}^S)] \quad (\text{A.2})$$

where  $\tau'_S$  and  $\delta_S$  are marginal tax and deduction rates at the state-level, net of federal deductions, and  $\hat{w}^S$  and  $\hat{p}^S$  are the differentials for state  $S$  as a whole relative to the entire country. These state tax rates should incorporate sales as well as income taxes, since sales taxes reduce the buying power of labor income. This tax differential may be added to (A.1) above to determine local quality of life.
