

# Non-Recourse Mortgage Law and Housing Speculation\*

Tong Yob Nam<sup>†</sup>      Seungjoon Oh<sup>‡</sup>

Dec 15, 2016

## Abstract

In a state with non-recourse mortgage law, borrowers have limited liability on their mortgage loan. Examining price discontinuities at state borders, we show that non-recourse law causes larger swings in housing prices by encouraging speculative investments when housing markets are in a boom cycle. We find that mortgage lending pricing does not fully reflect the higher risk in non-recourse state because the emergence of the originate-to-distribute (OTD) model in the housing markets enables lenders to effectively shift the risks to other investors. The amplified housing cycle has a real effect leading to higher households' consumption during a boom period.

# 1 Introduction

The wide swing in U.S. home prices in the early years of the 21st century can hardly be understood by the standard economic explanation based on fundamentals. Understanding and identifying the mechanisms that determine the boom-bust cycle in the housing market are thus central challenges that both financial economists and policymakers are facing. This paper builds on the previous literature to show that mortgage law plays an important role in the housing market. In particular, it sheds light on the effects of non-recourse mortgage law on the housing price cycle and mortgage lending by taking into account the growth of the mortgage securitization market.

U.S. mortgage law varies from state to state. Among many provisions included in mortgage law, non-recourse law governs lenders' right of deficiency judgment when borrowers default on mortgage loan payments.<sup>1</sup> Borrowers in recourse law states have full liability for their mortgage loans because lenders, in the event that foreclosure value is insufficient to meet the debt obligation, are able to claim other assets. Lenders in non-recourse law states are precluded from doing this and so bear some costs. Therefore, without proper pricing of the additional cost, the limited liability in non-recourse state gives rise to an asset substitution problem whereby borrowers increase risky investments and bid up prices. (Allen and Gale (2000))

The primary goal of this paper is to analyze whether non-recourse law affects the magnitude of boom-bust cycles in the housing market. The question is important because households portfolio choices are largely influenced by the housing price cycle and its volatility.(e.g., Flavin and Yamashita (2002), Cocco (2005), and Yao and Zhang (2005)) Particularly, higher housing price cycles may contribute to housing bubbles, and the feedback effects of subsequent crises significantly affect the real sector of the economy. Reflecting the importance of recourse law, the debate over recourse law has become controversial between scholars and policymakers (Pavlov and Wachter (2004, 2006), Ghent and Kudlyak (2011), Solomon and Minnes (2011), and Mitman (2011))

<sup>1</sup>Figure 1 identifies 11 states with non-recourse mortgage law.

and required extensive economic analysis to support housing system reform in many countries.<sup>2</sup>

The present paper focuses on a by-product of non-recourse law, namely, the social cost incurred as a consequence of households exploiting it by shirking their contractual mortgage obligations. Our key hypothesis is that non-recourse law amplifies the housing price cycle by encouraging risk-shifting behavior. Mortgage borrowers in non-recourse states, because they can walk away when house values fall below remaining mortgage amount (i.e., are “underwater”), have speculative motives to increase their risky investments (or increase their leverage, debt-to-income) in housing market. Our paper differs from previous literature that associates housing market collapse with a higher likelihood of strategic mortgage default by households in non-recourse states in a sense that we focus on the ex-ante households’ investment behaviors and identify the channel by linking with securitization market.

We first examine the housing price growth rates in pre- and post-mortgage crisis. Our main hypothesis is that non-recourse law causes housing speculation during the boom time driving the higher volatility in housing price. Using ZIP code-level housing prices from Zillow Real Estate Research between 2004 and 2009, we find evidence that housing prices in non-recourse states increased more during housing market booms, 2004-2006 and dropped more steeply during housing market recessions, 2007-2009. The economic impact of non-recourse law is large. Prior to the crisis, recourse states experienced 7% annual growth and the crisis reduced the housing price growth rate by 5%. But states with non-recourse law experienced 10% growth, and the corresponding drop in housing prices was 8%. Such stark differences in growth rates support the important impact of non-recourse law. We also calculate the growth rate using Federal Housing Finance Agency (FHFA) state-level house price index and find consistent evidence that housing price cycle is amplified in non-recourse states during our entire sample period. Unlike repeat-sales housing price data, our data do not control for

<sup>2</sup>“Full Recourse Loans Won’t Save Canada’s Housing Market”, 14 May 2013, CNBC, and “Heading to Non-Recourse Mortgage Financing? (Spain)”, 2011, Banking Law News, Azofra and Peruyero

the various characteristics, or hedonics, of houses. To mitigate this limitation, we use square footage housing price, and conduct additional estimations by the number of bedrooms. This finding remains robust. We also consistently demonstrate that the price-to-rent ratio commonly used as a measure of housing valuation increases during expansion and declines during recession more sharply in non-recourse than in recourse law states.

Empirically, however, it is difficult to distinguish the effects of non-recourse law from the effects of other characteristics that are unrelated to this state law. To circumvent this identification problem, we examine the effect of non-recourse law on housing prices by employing a state-border discontinuity design with the contiguous border county-pair sample. This identification strategy enables us to estimate the effect of recourse law on housing price cycles by controlling for fundamental property value and unobserved spatial heterogeneity. By directly comparing county-pairs in the state-border sample after including county-pair fixed effects, we further find that housing prices during the pre-crisis period increase upon crossing from recourse into non-recourse states whereas during the crisis prices decrease. These results are robust to consideration of state-level variation in bankruptcy laws, lending regulation and demographic heterogeneity.

We then document speculative investment behaviors of households in non-recourse states by showing a greater effect of non-recourse law in non-residential housing investments and households' higher leverage decisions than in recourse states. We expect that housing speculation is stronger among households with properties that are not primary residences and thus subject to less non-monetary utility loss from strategic default. Non-monetary costs that provide a disincentive to default, even with limited liability, include lowering of a defaulting household's credit rating and the utility loss of the foreclosed home and necessity to move. Consistent with this hypothesis, we find that the average housing price growth rate for borrowers with properties purchased either as second homes or for investment purposes is to be more greatly affected by non-recourse law during the pre-crisis period. We further find that debt-to-income ratio, defined as the total mortgage amount divided by annual household income, is

2-7 percentage points higher in non-recourse than in recourse law states for both prime and subprime borrowers. These results support our main argument that speculative investment encouraged by non-recourse law amplifies booms and busts in housing markets.

If this households' investment incentive is well predicted, however, mortgage lenders may behave differently. The excessive risk-taking behavior in non-recourse states can be prevented if mortgage loans are properly priced. More specifically, lenders can control the risk of borrower's default by means of low loan-to-value (LTV) ratios, high interest rates, and strict screening processes. Used appropriately, such tools can preclude borrowers from shifting risk and bidding up prices above fundamental values. Therefore, after establishing the relation between nonrecourse mortgage law and housing price growth, we examine the channel through which non-recourse law can lead to more speculative households housing investments.

First, we hypothesize that the emergence of the originate-to-distribute (OTD) model, together with credit expansion, enables lenders to effectively pass along the risks and reduces the screening incentive ex-ante (e.g., Keys et al. (2010) and Purnanandam (2011)), thereby promoting excessive loan originations in non-recourse states and amplifying the housing price cycle. Specifically, it is likely that securitization in a complex structure of financial derivatives effectively conceals the origins of loans. Piskorski et al. (2013) argue that the true quality of loans in the residential mortgage-backed security (RMBS) market has frequently been misreported to investors.

We further hypothesize that nationwide GSE (government-sponsored enterprise) loan policy drives underpricing of non-recourse loans, further fueling speculation in non-recourse states during boom periods. A large portion of mortgage loans are purchased by GSEs and, after being securitized, sold to the secondary market. Consequent to the anti-discretionary policy across states, however, originated loans are purchased by GSEs without proper pricing through higher guarantee fees. Hurst et al. (2015) shows that regulatory limitations in pricing loans allow mispricing in the OTD market across states, and subsidizes borrowers in states with higher costs. Households in non-recourse

states can thus borrow at relatively lower interest rates. This mispricing, compensated by taxpayers, can drive greater speculation in non-recourse states.

To demonstrate the channel for housing speculation, we use cross-sectional variation in risk-shifting intensity from the OTD model. The two-stage risk-shifting hypothesis (from non-recourse households to lenders, and from lenders to the securitization market) predicts that interaction with subprime mortgage expansion will promote greater housing speculation in non-recourse states during the pre-crisis period. Our finding that, in non-recourse states, ZIP codes with high subprime loan ratios experienced particularly large housing price increases during the boom period is economically and statistically significant, and robust to different numbers of bedrooms, with the effect particularly strong for smaller homes. Further supporting the hypothesis we find that the denial rate for loan applications, for both prime and subprime loans, is significantly lower in ZIP codes in non-recourse states. These results suggest that housing booms are likely to be larger in non-recourse law states because the OTD market dissuades lenders from controlling consequent risk and screening quality of loans.

Distinguishing between GSE, non-GSE, and bank portfolio loans for purposes of examining which types of mortgage securitization are responsible for the mispricing of non-recourse law, we find the ratios of non-GSE and GSE, and sum of GSE and non-GSE (securitized) loans to total mortgage loans to be associated with higher housing price growth in non-recourse states. These results are consistent with Keys et al. (2010) finding that weaker screening origination standards are applied to loans likely to be sold in the non-GSE secondary market. The results further suggest that, despite relatively stricter quality requirements, securitized GSE loans are potentially likely to promote further housing speculation due to regulatory limitations, supporting the second hypothesis.

Lastly, we examine whether amplified housing prices in the pre-crisis period in non-recourse states engender an increase in real household consumption consequent to relaxation of borrowing constraints and a perceived increase in wealth. Our finding that households in non-recourse states tend to increase consumption of non-durable

goods during the pre-crisis period, being focused on housing speculation and increased real consumption, differs from that of Mian et al. (2015), who found foreclosures instrumented by state judicial requirements to lead to a steeper decline in housing prices, residential investment, and consumer demand during the recession period.

In this paper, we first propose the causal relation between mortgage foreclosure law and housing speculation. This paper has important implications for the housing price boom in the early 2000s. Previous literature attributes the boom to low, long-term real interest rates managed by monetary policy (e.g., Himmelberg et al. (2005) and Taylor (2007)). Other literature maintains that certain superstar cities experienced significant housing price appreciation due to an inelastic supply of land and growing number of high income households (e.g., Glaeser et al. (2008) and Gyourko et al. (2013)), and Shiller (2007) asserts that the real estate boom during this period was driven by a “social epidemic of optimism” that encouraged speculative investment. Additionally, the role of credit supply in housing price dynamics has been explored in the literature. Favara and Imbs (2015) focus on US branching deregulations between 1994 and 2005 to identify credit supply shock and show the casual relationship between the supply of mortgage loans and house prices. Maggio and Kermani (2015) also examine the effect of credit supply on the boom and bust cycle in house prices and real economic activity by exploiting an enactment of a preemption rule which exempts national banks from state anti-predatory lending laws. Mian and Sufi (2009) show an effect of subprime mortgage expansion on house prices between 2002 and 2005. Our contribution to this literature, the suggestion that mortgage law has a significant impact on state variations in housing investment behavior and price patterns, enhances understanding of cross-sectional variation in housing prices across states.

In the literature, the effect of foreclosure and bankruptcy law on household economic behavior has been examined from various perspectives (Gropp et al. (1997), Fay et al. (2002), Li et al. (2011), Ghent and Kudlyak (2011), Dobbie and Song (2015), and Mian et al. (2015)). In particular, several papers reveal that mortgage foreclosure law affects household default decision when home values are underwater. Ghent and Kudlyak

(2011) shows that mortgage defaults are more frequent in non-recourse law states and quantifies the effect of recourse law on default, and Pavlov and Wachter (2004, 2006) proposes a model for the underpricing equilibrium of the put option embedded in non-recourse mortgage lending. Other recent studies provide a theoretical framework for households mortgage default decisions related to mortgage foreclosure law (Mitman (2011), Campbell and Cocco (2015), and Corbae and Quintin (2015)). Findings in the present paper are also closely related to those of Mian et al. (2015), who uses state laws on judicial requirements for foreclosure to investigate housing prices and trends in foreclosure. Our paper mainly differs from these studies in emphasizing the impact of non-recourse law on the housing boom-bust cycle and its interaction with mortgage lenders taking into account the growth of the mortgage securitization market.

The present paper also expands previous research on the recent mortgage crisis by providing some of the first evidence of the combined effect of mortgage law and the securitization market on housing markets. Together with significant credit expansion from low interest rate policies, the role of the housing market preceding the crisis is highlighted (e.g., Herring and Wachter (2003), Reinhart and Rogoff (2008, 2009), Mayer et al. (2009), and Makarov and Plantin (2013)). Many studies have suggested that subprime mortgage expansion promoted the unsustainable growth responsible for the market's collapse.<sup>3</sup> This paper extends previous research by showing how subprime mortgage expansion and the secondary mortgage (GSE and non-GSE) securitization market, by influencing lending behavior, accounts for variations in housing speculation across states and the impact of the mortgage crisis.

The rest of this paper is organized as follows. Sample data are described in Section 2. The definition and origins of recourse law are explored in Section 3. In Section 4, an empirical strategy is developed and the impact of recourse law on housing prices and household investment behavior examined. The impact of recourse law combining with mortgage securitization market analyzed in Section 5. Section 6 concludes.

## 2 Data and Summary Statistics

### 2.1 Housing Price Data

In this study, we use multiple sources of housing market data including Zillow Real Estate Research and Federal Housing Finance Agency (FHFA) house price index.<sup>4</sup> Using multiple sources of housing price data, we calculate annual housing price growth rate over the sample period of 2004-2009.

Particularly, our empirical works mainly rely on the housing market data from Zillow Real Estate Research ([www.zillow.com](http://www.zillow.com)). Widely used in related literatures (e.g., Huang and Tang (2012), Guerrieri et al. (2013), and Mian et al. (2015)) the Zillow database provides ZIP code-level housing price data at the monthly level from 1999-2013. The 36,577 ZIP codes in the Zillow.com data for 50 states represent 78% of U.S. ZIP codes. Using, for each ZIP code, as a measure of housing price the median home value scaled by a home's square footage reduces the total sample to around 11,000 major ZIP codes in 50 states. We calculate the rate of annual growth in housing price at time  $t$  based on the price in January in periods  $t$  and  $t+1$ .

We also employ as an alternative measure of the housing valuation the price-to-rent ratio. This ratio reflects the relative cost of owning a house relative to the fundamental value of the asset, present value of future rental value. A housing price overvaluation may generate an unsustainably high price-to-rent ratio. We acquire median rent value from American Community Survey data at the county level for the period of 2005-2010, and calculate the growth rate.

### 2.2 Subprime loan and Securitization

HMDA data provides comprehensive primary mortgage originations and secondary market loan purchases for individual one-to four family residential mortgages that a bank originated in each calendar year. Lenders are required to report origination information on borrower, lending institutions, and type of purchaser of mortgages.

---

<sup>4</sup>Purchase-Only Indexes, Estimated using Sales Price Data

As HMDA data do not include an indicator for whether a loan is subprime, various methodologies for identifying subprime borrowers are employed in the literature. We classify subprime loans based on lender identification and interest rate charged. We construct a subprime ratio measure specifically, the number of sub-prime mortgage loans out of the total number of mortgage loans originated, using a list of subprime lender specialists compiled annually by HUD (<http://www.huduser.org/portal/datasets/manu.html>). However, this subprime lender list is available until 2005. Therefore, we classify a loan as subprime after 2005 if the annual percentage rate (APR) is three percentage points above a comparable Treasury APR (i.e., if the mortgage spread is beyond three percentage points).

The “Type of Purchaser” includes whether the mortgage was sold in that calendar year and whether sold to a government-sponsored enterprise (GSE) or an affiliate institution for purchased loans. Using this data, we calculate the GSE, non-GSE and bank portfolio loan ratio to total originated loans for each county level. HMDA data has limited loan-level information relative to LPS, but it covers a wider set of loans (across GSEs and non-GSEs) being used in many previous literature to capture securitization. (i.e., Han et al. (2015)). HMDA data includes agency and non-agency mortgage-backed securities, and it covers 93.3 percent of FHA loans and 81.6 percent of GSE acquisitions.(Finance (1998))

## 2.3 Control Variables

To control characteristics of local housing market, we collect a variety of economic and demographic characteristics. The American Community Survey (ACS), Federal Housing Finance Agency (FHFA), and Federal Reserve Bank of New York provide county-level fraction of high education, population with age greater than 62, and married status. The ACS data include socioeconomic characteristics of households, such as population, income growth, and unemployment rate. We also collect other important state-level variation in mortgage foreclosure laws, judicial foreclosure.

## 2.4 Summary Statistics

Table 1 presents summary statistics of the state-level data used in our analysis. Table 1 shows that 11 states, or 22% of all state observations, have non-recourse mortgage law. The average housing price growth rate is around 1-2% during the sample period. It is noteworthy that annual housing price growth has a large variation during our sample period as a result of the collapse of housing prices during the mortgage crisis. The average housing price growth rate are 7.7% annually during the pre-crisis period from 2004 to 2006, and dropped by -4% during the crisis period from 2007-2009. The standard deviation of growth rates across states is also large. During the pre-crisis period, 10 percentile states experienced 3% increase while 90 percentile states experienced 14% increase. During the crisis period, 10 and 90 percentile states experienced -10 to 0% price growth. The average nominal GDP growth rate is 4%, the population growth is 1%, and the income growth rate is 2%, on average, during our sample period. The average fraction of NonGSE loan and Subprime loan are 51% and 15%, respectively.

## 3 Background of Non-recourse Mortgage Law

### 3.1 Definition of Non-recourse Mortgage Law

U.S. mortgage law varies across states in many important ways. State-level mortgage law can be classified as recourse and non-recourse, depending on lenders' right of deficiency judgment when borrowers default on residential mortgage loans. Recourse law permits lenders to claim, in other assets and salary, the difference between a remaining mortgage amount and the foreclosure value of a house. Non-recourse law allows lenders to seize only the collateralized house in the event of a mortgage default.

Although states are not strictly classified as recourse and non-recourse, it is widely accepted among both academics and practitioners that 11 states have non-recourse

mortgage laws.<sup>5</sup> Figure 1 illustrates the distribution of recourse and non-recourse law in the United States.<sup>6</sup>

## 3.2 Origins of Non-recourse Mortgage Law

State-level recourse law has changed little since its enactment during the Great Depression of the 1930s. During that economic recession, foreclosure sales were sufficiently intense and widespread to distort the housing market and caused houses to be sold below their fundamental value. However, mortgage lenders sold borrowers' properties at a deep discount and then claimed deficiency judgments for the full amount of the debt, which amplified the depression. This prompted the anti-deficiency judgment legislation enacted in many states (Solomon and Minnes (2011)).

How states with non-recourse mortgage laws were chosen is an important consideration, as selection on the basis of particular economic motives could imply an unobserved factor responsible for both the legislation and recent housing market dynamics. To mitigate concerns about reverse causality and omitted variable bias, we look to Ghent (2013), who provides historical perspective on how individual states enacted divergent foreclosure laws, in particular, the recourse provision, in the wake of the Great Depression. The paper's finding of no clear economic or legal reasons for states' development of different procedures in the event of mortgage default suggests that the differences relate mainly to judges' idiosyncratic interpretations of case law. In any case, that the differences have persisted little changed since the 1930s mitigates concerns about bias in our empirical results.

---

<sup>5</sup>There have been debates over the identification of non-recourse states between scholars. Zywicki and Adamson (2009) argue that 15-20 states have non-recourse laws while Ghent and Kudlyak (2011) estimate that eleven states have non-recourse laws. We mainly employ the classification of Ghent and Kudlyak (2011). But we also check the robustness with the other classifications. <http://www.foreclosurelaw.org/> provides a comprehensive description of state foreclosure laws in the United States.

<sup>6</sup>In Appendix A, we also compare recourse law with the judicial foreclosure requirement, one of the major mortgage foreclosure laws investigated in the literature (Mian et al. (2015)).

## 4 Non-recourse Law Effects on Housing Price

We attempt to understand in this paper whether the magnitude of housing price cycle reflects differences between recourse and non-recourse laws. We hypothesize that non-recourse law states experience a larger price increase during a housing market boom and a larger burst during a housing market recession. The asset substitution model by Allen and Gale (2000) provides the theoretical rationale for borrowers with limited liability investing aggressively in risky assets and creating a bubble by bidding up asset prices above their fundamental value.

### 4.1 Univariate Test

Our first set of tests investigates whether recourse law has an effect on housing price growth. Figure 2 presents the time-series behavior of the aggregate growth rate of housing price (Panel A) and price-to-rent ratio growth (Panel B) in recourse and non-recourse states. Although these growth rates move in a similar fashion, greater swing is observed in non-recourse states in both Panel A and B. NBER classifies the periods from March 2001 to November 2001 and December 2007 to June 2009 as recessionary periods. As can be seen in Panel A of Figure 2, the housing price growth rate is higher during the pre-crisis period of 2002-2005, but falls below that of recourse states during the recent crisis period from 2007-2011.<sup>7</sup> It is also worth noting that the housing price growth rate from 1998-2000 is higher, and drops more steeply during the first recessionary period in 2001, in non-recourse than in recourse states. Panel B of Figure 2 shows the price-to-rent ratio growth during the pre-crisis period to be positive and higher, and during the crisis decrease more, in non-recourse than in recourse states. Figure 2 shows a repeating pattern of a larger housing price swing in non-recourse states.

Table 2 compares the main housing market variables between recourse and non-recourse states. We hypothesize that housing prices in non-recourse states rise more

---

<sup>7</sup>The housing price growth rate declined sharply in 2006 but remained positive, which indicates that housing prices peaked in 2006.

during a housing market boom, and drop more steeply during a housing market recession. In Panel A, which compares recourse and non-recourse states in the pre-crisis period from 2004-2006, non-recourse states are seen to have higher ZIP code-level housing price growth, on average, by 3 percentage points annually, at the 1% significance level. County-level Price-to-rent ratio and MSA-level FHFA housing price index also show 3.6% and 1.8% annual growth rates, respectively. This is consistent with our hypothesis. On the other hand, during the crisis period in our sample, housing prices show a larger drop in non-recourse states. As can be seen in Panel B of Table 2, during the crisis period from 2007-2009, the ZIP code-level housing price growth rate declined, on average, by 5% annually in recourse, and 8% in non-recourse states. It should be noted that most of control variables are not significantly different between non-recourse states and recourse states. This implies that samples are relatively similar except the difference in mortgage law.

## 4.2 Multivariate Test

The previous results can be driven by other potential factors affecting housing market. Multiple complementary approaches are employed to identify a causal relation between recourse law and amplified housing price cycle. To separately capture the effects of nonrecourse law before and after the crisis, we apply the difference-in-difference specifications that exploit the nationwide credit supply shock of the mortgage market collapse in 2007 that affected states differentially. The identification of ZIP codes disproportionately affected by the crisis enables us to estimate regressions as follows,

$$\Delta \ln(P_{it}) = \beta_0 + \beta_1 \text{Non-recourse}_i + \beta_2 \text{Recession}_t * \text{Non-recourse}_i + \beta' X_{it} + \theta_t + \varepsilon_{it}$$

where the dependent variable,  $\ln(P_{it})$ , is the growth rate of housing price per square foot in ZIP code  $i$  at time  $t$  from 2004-2009,  $\text{Recession}_t$  is a dummy variable equal to zero before and including 2006 and one after that year,  $\text{Non-recourse}_i$  is a dummy variable equal to one if ZIP code  $i$  is located in a non-recourse state, and zero otherwise.

The annual nationwide housing price growth rate was 8%-11% from 2002-2005, dropped to 2.3% in 2006, and in 2007 turned negative and remained so until 2011. We therefore define  $Recession_t$  as a dummy variable equal to zero before and including, and one after, the year 2006.

In this specification, the main coefficient of interest is the coefficient on non-recourse dummy,  $\beta_1$ , which captures the average difference in housing price growth by non-recourse law before crisis period. The coefficient on the interaction term between non-recourse dummy and  $Recession$  dummy,  $\beta_2$ , captures the differential impact of the crisis on housing price growth rates in recourse and non-recourse states. If non-recourse law causes a larger speculation in the housing market, the crisis may precipitate a disproportionately larger drop in housing price in non-recourse states. Our hypothesis predicts a positive sign on  $\beta_1$  and negative sign on  $\beta_2$ .

This difference-in-difference estimator suggests a relation between non-recourse law and housing market speculation. However, this estimator can be confounded if housing prices are affected differently for reasons unrelated to recourse law. We address this problem by including the set of other state-level control variables,  $X_{it}$ , that potentially affect demand in the local housing market, such as annual GDP growth, per capita income growth, and population growth rate. We also include county-level demographic variables from Census data such as age (proportion of the population aged 60 or above), female population ratio, education level, and marriage status of households, which are likely to be a source of omitted variables bias. Other state- and MSA-level controls increase precision.

We include a dummy variable for *Judicial Foreclosure*, another major state-level law that sets forth judicial requirements in the foreclosure process. Other literature (Pence (2006), and Mian et al. (2015)) indicates that state-to-state variation in judicial foreclosure law is an important determinant of mortgage credit and foreclosure rates. Lastly, we include year fixed effects,  $\theta_t$  to capture the national wide changes in housing market condition for each year. The standard errors are clustered county-year level.

In Table 3, the first model estimates the non-recourse law effect on housing price growth (HP growth) for the full sample with control variables. The estimates show that housing price growth in non-recourse states is higher than in recourse-states in the boom period but falls more after the mortgage market collapse. A positive and significant coefficient on the *Non-recourse* dummy variable indicates that housing prices have grown higher by 3.1% annually, in non-recourse than in recourse states during the pre-crisis period. In particular, the estimated coefficient on the interaction term shows that housing prices dropped more in non-recourse states during the crisis. The negative difference-in-differences produced by these changes is consistent with non-recourse states generating a larger speculation. The economic magnitude of the interaction effect is 5.6%, and the coefficient is significant at the 1% level. This indicates that housing prices declined more in non-recourse states than recourse states by 5%-6% annually during the crisis period. It is noted that all the control variables have intuitive signs of coefficients. Economic attributes such as the growth rates of GDP, population, income are positively associated with the housing price growth. The portion of age over 62 and the married status are negatively associated with the housing price growth.

We examine the effect of non-recourse law on the housing valuation directly using the price-to-rent growth rate. Since rent is a long-run indicator of a property's fundamental value, the price-to-rent ratio captures the effect of non-recourse law on speculative bubbles in the housing market. We employ an identification strategy identical to that of previous regressions for the sample period from 2006-2009. Table 3 presents the estimates for regression of the price-to-rent growth rate on non-recourse law. Consistent with the previous results on housing price growth, we show that, relative to the present value of future rental or "fundamental value," housing prices before and during the crisis appreciate and fall, respectively, by 4.5 and 4.3 percentage points more in non-recourse than in recourse states.

The ideal home price index would be repeated sales price for same house for every year. However, since house sales do not occur each period, we rely on the estimated value by Zillow which uses sales prices for the same set of houses in each time period.

For every ZIP code, we use the median values of homes located in each ZIP codes scaled by square footage of a home. Zillow database provides both median sales price and estimated home value using a time series tracking the monthly median home value in a particular geographical region. The detail estimation methodology is described in the following webpage (<http://www.zillow.com/research/zhvi-methodology-6032/>). For robustness, we employ an alternative source of housing price growth rate calculated based on the FHFA MSA-level housing price index for the sample period. Consistent with the results based on Zillow housing price, Table 3 shows that the growth rate of housing price index (HPI index (FHFA)) is larger in non-recourse states during the pre-crisis period by 2.8%, while the price index declines more sharply during the crisis by 6.0%. The coefficients are statistically significant at 1% level.

Our housing data has a another limitation since we cannot control for the various property attributes, or hedonics, of houses. The median-price measure for square-footage we are using assume constant composition and quality of houses across sale dates. Hedonic regression pricing with a vector of property characteristics mitigates the constant quality limitation, however, it is challenging in dearth of data limitation. Thus, we use housing price growth rate by the number of bedrooms and conduct the same regressions, which mitigates the concern on potential unobserved characteristics of house. The results are robust to the different number of bedrooms. In Table 3, while the magnitudes of coefficients for non-recourse dummy and interaction term vary by the number of bedrooms, the results are consistent with the previous findings. The effect of non-recourse law on housing price during the expansion period increases with the number of bedrooms.

There is another potential concern that some of the control variables are endogenously determined with housing price  $P_{it}$ . For example, households that expect increases in property price may increase consumption. We address this possibility by performing the regression with lagged variables for time-varying controls. In the unreported results, we run the regression using the lagged variable for state-level, time-varying controls like GDP, income, and population growth. The results imply that our

main results are robust to the endogeneity problem between housing price growth and the control variables.

### 4.3 State-Border tests

The previous regression is still unable to control for unobserved spatial heterogeneity. Two randomly selected locations, identical except for recourse law status, provide an ideal empirical setting for our experiments. There are, however, a biggest challenges to examining the causal relation is in the absence of a randomized experiment, unobserved heterogeneity may lead to omitted variable bias. Many other characteristics, such as preference for home ownership, dwelling patterns, and state-specific laws and policies, may affect the return on housing assets. Also, substantial heterogeneity may be observed in housing and demography within large states.<sup>8</sup>

This concern can be mitigated because we observe no systematic difference in economic and social attributes across recourse and non-recourse states from our summary statistics. To suggest further evidence, we control for unobserved spatial heterogeneity by performing difference-in-difference regressions at the ZIP code-level using the same explanatory variables, but focused on counties close to a border between states with different recourse laws. We include county-pair fixed effects to capture county-pair specific characteristics. A number of studies have used the state border effects methodology to explore how differences in the socioeconomic environment affect various factors across counties and states (e.g., Holmes (1998), Pence (2006), Dube et al. (2010), and Mian et al. (2015)).

Our framework for examining the impact of recourse law by exploiting the discontinuity at state borders combines the strategy employed in Pence (2006) and Mian et al. (2015) with a difference-in-difference setting less susceptible to unobserved variation

---

<sup>8</sup>For example, New York’s Erie County and Westchester County have similar populations of 0.75 million, but median household income levels of \$47,533 and \$77,006, respectively, whereas Connecticut’s Fairfield County is contiguous with, and has socioeconomic characteristics similar to those of, Westchester county.

over time. We run the following regression,

$$\Delta \ln(P_{it}) = \beta_0 + \beta_1 \text{Non-recourse}_i + \beta_2 \text{Non-recourse}_i * \text{Recession}_t + \beta' X_{it} + \theta_t + \phi_i + \varepsilon_{it}$$

where  $\Delta \ln(P_{it})$  is the average growth rate of housing price in ZIP code  $i$  at time  $t$  from 2004-2009 and  $\text{Non-recourse}_i$  is an indicator that identifies whether ZIP code  $i$  is located in a non-recourse state. The county-pair sample regression captures the jump, or discontinuity, at the state border. We include the county-pair fixed effect  $\phi_i$  to capture the variation between contiguous counties along a state border. Standard errors are heteroskedasty consistent and clustered at the county level. The coefficient on  $\text{Non-recourse}$  captures a sharp discontinuous change in housing price when a border is crossed into a recourse state.

In Table 4, we present results for the contiguous state border county-pair sample with the county-pair fixed effect. This specification enables us to control for unobserved spatial heterogeneity. The coefficients on the  $\text{Non-recourse}$  dummy variable is consistent with the previous result. We find negative and significant coefficients on the interaction term  $\text{Non-recourse} * \text{Recession}$  in these models as well. The economic magnitude of the estimate on non-recourse is 2-4% depending on the number of rooms. The results indicate that during the crisis housing prices drop more in non-recourse than in recourse states, especially at state borders.

## 4.4 Robustness Tests

We report here the results of robustness tests performed to address concerns that heterogeneity and self-selection could drive our main results.

We consider, in particular, state-level variations in personal bankruptcy law and lending regulation that are potentially correlated with the non-recourse/recourse difference. Variations in bankruptcy homestead state laws that protect home equity from creditors up to a state-specified exemption amount in case of personal bankruptcy, for example, affect households' incentive to default (Dobbie and Goldsmith-Pinkham

(2014)), and also to speculate during boom periods. We examine whether the effects of non-recourse law are robust to consideration of the homestead exemption amount. We also control for state foreclosure timelines for completing uncontested foreclosures, and check whether our results are affected by state-level anti predatory lending laws. In 1994, the US Congress passed the Home Ownership and Equity Protection Act (HOEPA) to regulate interest rates for high-cost loans. We use the state index for HOEPA laws from Bostic et al. (2008), which captures the extent of the anti predatory lending laws coverage, restrictions, and enforcement. Table 5 shows that our main results are robust to inclusion of these state-level variations.

We also control for county-level housing supply elasticity, from Glaeser et al. (2008), and, to capture ex ante differences in credit supply, the Herfindahl Hirschman Index for bank competition based on state-level total deposits. The re-estimation results reported in Table 5 are similar to those reported in Table 3.

We address the concern that the effect of non-recourse mortgage provisions on housing speculation might vary with states understanding of the differences between recourse and non-recourse mortgage law by controlling for state-level financial literacy using indicators based on Lusardi and Mitchell (2014) and National Financial Capability Study data. Models (1)-(3) in Table 6 show that our results to be are robust to controlling for state-level financial literacy.

We address a potential concern that some states may experience a higher influx of foreign investors (e.g., Vancouver experiences rapid housing price growth due to Chinese investors) and subsequent housing price increases by controlling for state-level variation in the influence of immigrants. Models (4)-(6) in Table 6 show that the effect of non-recourse law on housing price growth to be is unchanged after controlling for the total number and growth of immigrants, and proportion of Asian immigrants, in each state.

Lastly, Models (7)-(9) in Table 6 show that the effect of non-recourse law on housing price growth remains consistent after controlling for states political characteristics (i.e., red states versus blue states) and industry composition.

## 4.5 Evidence of Housing Speculation

Housing plays a dual role as investment and residence. While the investment purpose of housing is important for homeowners as housing usually takes a great portion of their total asset, other factors such as job location and neighborhood are also critical for their decision on home purchase. On the other hand, housing investors who buy solely with investment purpose mainly take into account the gain from housing investment, and they are more likely to invest in housing market with speculative motive. In this regard, we conjecture that housing investors respond more sensitively to mortgage recourse law since the law can directly affect the gain on their investment, and therefore, the effect of non-recourse law on housing prices would be amplified in areas where housing investors abound.

To test this hypothesis, we first estimate the proportion of investment purpose transactions relative to residential purpose in a specific area using occupancy variables in HMDA data. We then examine how the effect of mortgage recourse law on house price varies with the proportion of housing investors. More specifically, we use the following regression specifications.

$$\Delta \ln(P_{it}) = \beta_0 + \beta_1 \text{Non-recourse}_i * \text{High Invest}_{it} + \beta_2 \text{High Invest}_{it} + \beta_3 \text{Non-recourse}_i + \beta' X_{it} + \varepsilon_{it}$$

where  $\text{High Invest}_{it}$  is the dummy that equals one if the proportion of housing investors in ZIP code  $i$  is greater than the sample median, zero otherwise, and  $\text{Non-recourse}_i$  an indicator for whether ZIP code  $i$  is located in a non-recourse state.

Table 7 shows the result of this regression. The coefficient  $\beta_2$  is positive and statistically significant, implying that areas where investors abound experience higher house price appreciation. The coefficient  $\beta_1$  is positive and statistically significant, implying that the effect of non-recourse law on house price is stronger if the portion of investment purpose transactions is high relative to residential purpose. The effect is particularly significant for houses with two- and three-bed rooms. In sum, the effect of non-recourse law on house price appreciation is amplified in areas with high portion

of housing investors relative to homeowners since housing investors have more chance to exploit the benefit of non-recourse law to maximize the gain from their housing investment.

## 4.6 Household Leverage Decisions

We investigate the source of a larger housing price cycle in non-recourse states by examining the impact of recourse law on household debt-to-income decisions. The housing price pattern in non-recourse states is likely to reflect household speculative behavior. Limited borrower liability, because it may encourage highly leveraged investments that have the potential to increase returns without incurring additional downside risk, may lead households to invest with a higher debt-to-income ratio. To examine households' speculative investment motive, we construct average debt-to-income ratio at ZIP code-level using HMDA data as a proxy for the leverage decision of households investment in the housing market. The DTI ratio is the total mortgage amount divided by annual income at origination date. HMDA data includes borrowers' individual mortgage amount and income level at mortgage origination. We estimate the effect of non-recourse law on debt-to-income using the following specification,

$$DTI_{it} = \beta_0 + \beta_1 Non-recourse_i + \beta' X_{it} + \theta_t + \varepsilon_{it},$$

where  $DTI_{it}$  is the debt-to-income ratio, or borrower's total mortgage lending divided by annual income from HMDA data, at loan origination in ZIP code  $i$  in year  $t$ , and  $Non-recourse_i$  an indicator for whether ZIP code  $i$  is located in a non-recourse state. We also include the year fixed effect  $\theta_t$ . Standard errors are robust to heteroskedasticity and clustered at the county-year level. In this specification, the coefficient  $\beta_1$  on the non-recourse indicator shows whether households' debt-to-income ratio is higher in non-recourse states.

Table 8 shows that debt-to-income ratios associated with households' investments in housing assets tend to be higher in non-recourse states. We present the results for

the full sample loans in Models (1) and (2), for the total sample period and the pre-crisis period, respectively. In Models (3)-(4), we present the results for the prime loan sample for the total sample period and the pre-crisis period, respectively. *Non-recourse* dummy in all Models (1)-(4) yields positive estimates statistically significant at the 1%-5% level. The coefficient estimate of 0.063 in Model (1) indicates that households in non-recourse states borrow around 2 percentage points ( $0.063/2.117=2.97$ ) more debt on average given the same income. The speculative behavior is more significantly observed in prime loan. The coefficient estimate in Model (3) is 0.091, indicating that households in non-recourse states borrow 7 percentage points ( $0.091/2.117=4.3$ ) more debt given the same income for borrowing prime loans. The results support the evidence of speculative motives for investing in non-recourse states.

Taken together, these results suggest that, because the risk-shifting feature of non-recourse mortgage law promotes riskier investments in housing purchases, housing prices experience a larger boom in non-recourse than in recourse states.

## 5 Non-recourse Law and Mortgage Securitization Market

After establishing the relation between non-recourse mortgage law and speculation in housing market, we attempt to identify the channels. If this households' investment incentive is well predicted, mortgage lenders may behave differently. The excessive risk-taking behavior in non-recourse states can be prevented if mortgage loans are properly priced. More specifically, lenders can control the risk of borrower's default by means of low loan-to-value (LTV) ratios, high interest rates, and strict screening processes. Used appropriately, such tools can preclude borrowers from shifting risk and bidding up prices above fundamental values. In this section, therefore, we examine channel through which non-recourse law can lead to more speculative households housing investments.

## 5.1 Non-recourse Law and Subprime Mortgages

First, we conjecture that the larger housing price cycle observed in non-recourse states notwithstanding lender efforts to control for the additional risk is attributable to the emergence of the originate-to-distribute (OTD) market that enables lenders to effectively shift the risk of those costs to other investors. In other words, mortgage lending behavior does not fully reflect the higher risk in non-recourse states. The literature suggests that the OTD market, by enabling mortgage lenders to securitize mortgage loans and resell them to third parties, mitigates constraints in credit supply and the ex-ante incentive to screen borrowers (Keys et al. (2009, 2010), Keys et al. (2012) and Purnanandam (2011)).<sup>9</sup> It is likely that the multiple stages of securitization in a complex structure of financial derivatives effectively conceal the origins of loans. Furthermore, Piskorski et al. (2013) argue that the true quality of loans in the residential mortgage-backed security (RMBS) market has frequently been misrepresented to investors. They show that for one in ten loans in the RMBS market borrower occupancy status or second lien information is misrepresented and thus not priced in the securities at issuance.

To the extent that it does not reflect the embedded risk in non-recourse mortgage loans, the OTD market promotes a disproportionately large increase in speculative investments in non-recourse states. This is consistent with the argument that the OTD model induces excessively risky mortgage loan originations (Pennacchi (1988) and Gorton and Pennacchi (1995)). Particularly, subprime mortgage loan origination is likely to be associated with loans with poor quality and lax screening incentive. We test this relation by estimating the interaction effect of the *Non-recourse* dummy variable and ZIP code-level fraction of subprime mortgage loan origination ratio, defined as the number of subprime mortgage loans divided by the total number of mortgage loans originated, during the pre-crisis period. We use the following specification,

$$\Delta \ln(P_{it}) = \beta_0 + \beta_1 \text{Non-recourse}_i * \text{Subprime}_{it} + \beta_2 \text{Subprime}_{it} + \beta_3 \text{Non-recourse}_i + \beta' X_{it} + \theta_t + \varepsilon_{it}$$

---

<sup>9</sup>Rapid expansion of this market was accompanied by relaxation of the regulation of mortgage lending.

where the dependent variable is the growth rate of housing price per square foot in ZIP code  $i$  at year  $t$  in the pre-crisis period. Year fixed effects are included and all standard errors are robust to heteroskedasticity and clustered at the county-year level. The interaction term between  $Non-recourse_i$  and  $Subprime_{it}$  is the main variables of interest. Our hypothesis predicts a positive coefficient, or  $\beta_1 > 0$ .

Table 9 presents the results of the regression that tests whether non-recourse law interacting with OTD lending drives greater housing price increases in non-recourse states. This test emphasizes a channel through which sub-prime mortgage expansion disinclines lenders in non-recourse states to control for the excessive risk in loan origination.

In literature, subprime mortgage loan is positively associated with housing price growth rate. Consistent with previous literature, we find that housing price shows a larger increase during the pre-crisis period when the ratio of the subprime loan is higher, an effect statistically significant at the 1% confidence level.<sup>10</sup> The positive and significant coefficients on the interaction between subprime and non-recourse states in Models (1)-(5) support our hypothesis. We employ the full sample for the pre-crisis period with control variables in Model (1), and separately estimate by the number of bedrooms using the same specification. The interaction effects remain positive and economically and statistically significant across models.

The economic magnitude of this effect can be interpreted as housing price growth 1 to 2.8 percentage points higher with a one standard deviation increase in the subprime loan ratio.<sup>11</sup> The interaction effect between non-recourse law and subprime ratio is largest for 1-bedroom homes and decreases over the bedroom number. Furthermore, it is interesting to note that the non-recourse dummy becomes insignificant when the interaction effect is included, which supports the importance of subprime channel we suggested in this paper.

---

<sup>10</sup>The coefficient on subprime ratio is positive and significant in the regression estimates without employing non-recourse law or its interaction with the sub-prime ratio.

<sup>11</sup>The standard deviation of the ZIP code-level sub-prime loan ratio is 0.18 for the pre-crisis period. The economic magnitude is calculated as  $0.18 \times 0.159 = 0.028$  in Model (2).

To further suggest the underlying evidence of two-stage risk shifting hypothesis, we test whether denial rates for loan applications differs between recourse and non-recourse states. The null hypothesis predicts denial rate to be higher under non-recourse law because lenders are expected to require stricter screening to control the additional risk in non-recourse states. On the other hand, our alternative hypothesis predicts denial rate to be lower under non-recourse law because the subprime mortgage market enables lenders to pass-through the risk to the other investors in the economy. The mortgage application can be denied by the financial institution. The reasons for denial are variously related to (1) debt-to-income ratio; (2) employment history; (3) credit history; (4) collateral; (5) insufficient cash (downpayment, closing costs); (6) unverifiable information; (7) incomplete credit application; (8) denied mortgage insurance; and (9) other. Because we aim to calculate the denial rate consequent to a high risk of insolvency, we estimate the fraction of loan applications denied for reasons 1, 3, 4, or 5, listed above. The regression specifications for these tests are as follow,

$$Denial\ Rate_{it} = \beta_0 + \beta_1 Non-recourse_i + \beta' X_{it} + \phi_i + \varepsilon_{it},$$

where  $Denial\ Rate_{it}$  is the average denial rate in ZIP code  $i$  at year  $t$ . Our main hypothesis predicts a negative coefficient on  $Non-recourse_i$  dummy, which corresponds to  $\beta_1 < 0$ .

We test denial rates for prime loans and subprime loans separately, to control for basic loan quality. We also test both total sample period and pre-crisis period. In Table 10 Model (1), the dependent variable is the denial rate for prime loans for the period of 2004-2009. The result indicates that aggregate denial rate of mortgage application in non-recourse states is 1% lower than in recourse states. The effect is larger during the pre-crisis period, 2004-2006. The results remain significant for subprime loans.

## 5.2 Non-recourse Mortgage Law and GSE Anti-discretionary Policy

We next examine whether lenders in non-recourse states underprice mortgage loans because of cross-state anti-discretionary policy. The securitization market differs sharply between GSEs and Non-GSEs.<sup>12</sup> We calculate GSE, non-GSE and portfolio loan ratios for each county using HMDA data. GSEs like Fannie Mae and Freddie Mac, which purchase, securitize, and sell to the secondary market a large portion of mortgage loans, offer guarantees that limit the risk of capital losses, enabling mortgage originators to increase loan volumes. Fannie Mae and Freddie Mac charge upfront and ongoing guarantee fees based on risk attributes of borrowers or loan type (such as LTV/credit-score grid, cash-out refinance, investor properties, secondary financing at origination, and jumbo conforming loan). Most lenders convert GSE guarantee fees into the interest rate on the mortgage, paid by borrowers over time.<sup>13</sup>

Because political influence prevents GSEs from pricing state-level variation in risk, mortgage rates for GSE loans do not differ significantly despite substantial differences in household bankruptcy provisions, foreclosure laws, and home exemptions across states.(Hurst et al. (2015))<sup>14</sup> The potential channel is thus that nationwide GSE loan policy that subsidizes borrowers in non-recourse states can drive taxpayer covered underpricing of non-recourse loans and engender further housing speculation during boom periods. This hypothesis predicts that a higher ratio of GSE loans can lead to state-level underpricing of non-recourse mortgage loans and increased housing speculation. We estimate the differential effects of GSE and non-GSE loans by examining the interaction effects between types of securitization and non-recourse law.

Table 11 reports estimation results for interactions between types of securitization (e.g., non-GSE, GSE, and sum of both) and non-recourse law. In Model (1), the

---

<sup>12</sup>Agarwal et al. (2012) analyze securitization strategy of lenders before pre and after post the crisis using multiple loan-level data sets.

<sup>13</sup>FHFA is directing GSEs to increase upfront fees by 25 basis points for loans for which the LTV ratio is greater than 80 percent or the credit score below 700.

<sup>14</sup>FHFA proposed in 2012 to impose an upfront fee on newly acquired single-family mortgages originated in states with laws likely to occasion for GSEs default-related losses much higher than the national average.

positive and significant coefficient on the interaction term between non-GSE ratio and non-recourse law confirms the previous findings on the subprime channel, and further shows that the total securitized loan ratio in Model (2) also increases the housing price growth rate in non-recourse states. These results are consistent with Keys et al. (2010) finding that weaker screening origination standards are applied to loans likely to be sold in the non-GSE secondary market.

Including both interaction terms between non-GSE and GSE loan ratios and non-recourse law, we find the interactions between non-GSE loan ratio and non-recourse law indicator, and GSE loan ratio and non-recourse indicator, to exhibit positive and significant coefficients on the housing price growth rate. The results suggest that, despite relatively stricter loan quality requirements, securitized GSE loans are also likely to spur further housing speculation, likely due to regulatory limitations, supporting our second hypothesis.

In the aggregate, our results demonstrate an underlying mechanism in recent housing speculation and explain why larger cycles are observed in non-recourse states. These results are consistent with our hypothesis, which states that the OTD market encourages greater risk shifting by lenders in non-recourse than in recourse states.

## **6 Non-recourse Mortgage Law and Households Consumption**

Lastly, we examine the real effects of housing price change. Increases in housing price can relax households borrowing constraints and increase perceived wealth. How households increase consumption in response to housing price increases has been studied in the previous literature.(i.e., Campbell and Cocco (2007))

Because housing accounts for the largest portion of most homeowners total wealth, variation in housing value affects household consumption through either the wealth effect or borrowing constraint channel. During the most recent housing market boom

and bust, households experienced a large fluctuation in housing value, which may have significantly influenced household consumption. Based on evidence provided above that housing prices in non-recourse states increased more rapidly during the housing market boom, we conjecture that the consumption growth rate was higher in non-recourse than in recourse states during this period.

Particularly, we expect the real effects to be stronger for households with higher age and lower income. (Campbell and Cocco (2007)) Home ownership rate is increasing in age, and home equity shares of the elderly tend to be high, as they pay off a large proportion of their mortgages. The high home ownership rate and low loan-to-value ratio among the elderly may partially explain the strong relationship between non-recourse law and consumption growth in this group. For the low-income group, the housing asset may play an important role as collateral. An increase in housing price, by relaxing the borrowing constraint, can afford the low-income group an additional channel for increasing consumption. Housing price increases can thus have a significant effect on consumption growth among the low-income group, and a relatively weaker effect in the high-income group, which already has another channel for borrowing.

We examine here, using state-level per capita consumption growth data provided by the Bureau of Economic Analysis, whether the difference in housing price growth is reflected in differences in the consumption growth rate between recourse and non-recourse states between 2004 and 2006. Following the existing empirical literature, we focus on non-durable consumption. Table 12 shows mean and median state-level non-durable goods consumption growth rates under non-recourse mortgage law. Although consumption growth rates exhibit no significant differences in the pooled sample, we find consumption growth rates among the high age and low-income groups to be substantially higher in non-recourse than in recourse states.

Table 13 examines the effect of recourse law on consumption growth rates using a regression model. We regress state-level per capita consumption growth rates on the mortgage recourse law indicator after controlling for such other state-level variables as GDP and population growth rates. Our finding that non-recourse mortgage law indi-

cators have significant and positive coefficients when we use the consumption growth rates of high age and low-income groups is consistent with the summary statistics in Table 13 and earlier findings reported in Campbell and Cocco (2007).

## 7 Conclusion

In this paper, we investigate the role of state-level variation in non-recourse mortgage law in generating a larger price cycle in the housing market. The results show that states with non-recourse law experience a larger expansion and burst in housing prices. Although the recent boom and bust in the US is characterized by unprecedented national-wide increase and decline, our results suggest that cross-sectional differences across states address a significant portion of housing price cycle and contribute our understanding of housing markets in this period.

The effects are economically large and robust to property attributes, and state-level variations in economic and demographic conditions. Our evidence supports the asset substitution problem in housing market and households' speculative investment behaviors in non-recourse states. The combined effects of non-recourse law and securitization intensity on the housing speculation suggests that the OTD market constitutes a disincentive to lenders to control and properly price for that risk, by enabling them to effectively shift it to other investors.

The boom and bust cycle in the housing market has been repeated and amplified in non-recourse states. Recourse mortgage law, although adopted by most European countries and Canada, China, and Japan, has become a subject of heated debate in relation to housing market reform. This paper identifies important implications for the evaluation of non-recourse mortgage law with respect to preventing future housing market crises and collapse. Non-recourse law, while protecting households from premature foreclosure and lenders' deficiency judgments, causes larger swings in housing prices as a consequence of being exploited by households to make riskier investments when housing markets are in boom cycles.

# APPENDICES

## A Variable Definitions

- *Non-recourse* is a dummy variable that equals one if the state does not allow lenders to claim deficiency judgments in the event of mortgage default, zero otherwise.
- *Recession* is a dummy variable that equals zero before and including 2006, and one after that year.
- *HP Growth (Sq. Ft)* is the annual growth rate of the ZIP code-level median of home value scaled by a homes square footage using Zillow database.
- *HP Growth before/after* is the annual housing growth rate for 2004-2006, and HP Growth after is for 2007-2009.
- *HPI growth (FHFA)* is the annual growth rate of the housing price index from FHFA data.
- *Price/rent growth rate* is the annual growth rate of the county-level median rent value divided by the county-level median housing price from the American Community Survey data from 2006-2009.
- *HP growth 1bed, 2bed, 3bed, and 4bed* are the annual growth rate of square footage housing price growth rate of home with a specific number of bedrooms.
- *Debt-to-income* is defined as the total mortgage amount divided by borrower's annual income at origination date.
- *GDP growth rate* is the annual growth rate of nominal GDP.
- *Income growth* is the growth rate of per capita income.
- *Pop growth* is the annual population growth at the county-level.
- *Edu high* is the proportion of population with college education at the county-level.
- *Age over 60* is the proportion of population with age greater than 60 at the county-level.
- *Female Ratio* is the proportion of female population at the county-level.
- *Married* is the proportion of population with married status at the county-level.
- *High Invest* is the dummy that is one if the proportion of non-residential purpose transactions is greater than the sample median, and zero otherwise.
- *Subprime ratio* is the aggregate ratio of the number of sub-prime mortgage loans to the total number of mortgage loans originated at the ZIP code-level.
- *Denial rate* is the ZIP code-level average denial rate of prime loan in a certain year.
- *Denial rate subprime* is the ZIP code-level average denial rate of subprime in a certain year.
- *GSE ratio* is the aggregate ratio of the number of Government-sponsored enterprises mortgage loans to the total number of mortgage loans originated at the county-level.

- *NonGSE ratio* is the aggregate ratio of the number of non-GSE mortgage loans to the total number of mortgage loans originated at the county-level.
- *Securitization* is the aggregate ratio of the sum of number of non-GSE mortgage loans to the total number of mortgage loans originated at the county-level.
- *Portfolio ratio* is the aggregate ratio of the number of loans in bank portfolio to the total number of mortgage loans originated at the county-level.
- *Judicial* is the dummy variable that is one if the lenders in the state are required to go through the courts for a foreclosed sale.
- *Property Tax* is the state-level property tax.
- *Homestead exemption* is the state-specified households' home equity exemption amount in case of personal bankruptcy by homestead state laws.
- *Foreclosure timeline* is the state-level foreclosure time lines to complete an uncontested foreclosure.
- *HOEPA index* is the state-level index for anti-predatory lending laws (Home Ownership and Equity Protection Act) during 2004-2005.
- *Housing supply* is the MSA-level housing supply elasticity.
- *HHI Bank* is the Herfindahl Hirschman Index for banking competition based on total deposit.
- *Fin Literacy1-3* are the state-level financial literacy indices related to compound interest, inflation, and stock risk, respectively.
- *Immigrant 2000* is the proportion of immigrants for each state in 2000.
- *Immigrant increase* is the growth rate of immigrant between 2000 and 2014.
- *Immigrant Asian* is the proportion of Asian immigrants for each state in 2014.
- *Red states* is a dummy variable that equals one if the state predominantly vote for the Republican Party in 2004.
- *Industry composition* is the average GDP share of manufacturing sector in each state during 2005-2007.

## B Comparison with Judicial Requirement

U.S. states have different laws regarding mortgage foreclosure. One of related provisions in mortgage foreclosure laws is judicial foreclosure requirement. In judicial foreclosure states lenders are required to go through the courts for a foreclosed sale whereas in non-judicial foreclosure states lenders have the own right to sell the property when borrowers are behind schedule on mortgage payments. According to Mian et al. (2015), twenty states are classified as judicial foreclosure states. Non-recourse states are mostly located in West coast and upper Midwest while the judicial foreclosure laws are mostly enacted in East coast. Among eleven non-recourse states, three states (Iowa, North Dakota and Wisconsin) have the judicial foreclosure requirement. Ghent (2013) and Mian et al. (2015) argue that the joint distribution of the mortgage laws were not caused by a certain economic reason or state-level policy differences.

Impacts of the judicial foreclosure requirement on the supply of mortgage loans and house prices have been examined by Pence (2006) and Mian et al. (2015). Pence (2006) finds that the judicial foreclosure requirement reduces mortgage credit supply by imposing greater costs on lenders seeking foreclosures on houses. Mian et al. (2015), on the other hand, highlight that non-judicial foreclosure requirements have a significant negative impact on house prices by increasing the supply of houses through the foreclosure process. Non-recourse law, which is not emphasized in these studies, clearly differs from the judicial foreclosure requirement. Although the judicial requirement has an effect on the foreclosure decision of homeowners, the liability of borrowers is distinct from this judicial process. The judicial requirement does not protect borrowers from unlimited liability.

Figure 1: State-level Variation in Mortgage Recourse law

This figure illustrates the classification of mortgage recourse law. States shaded in dark are non-recourse states. These states with non-recourse law are Alaska, Arizona, California, Iowa, Minnesota, Montana, North Carolina, North Dakota, Oregon, Washington, and Wisconsin.

Figure 2: Recourse Law and Housing Price Growth Rate

This figure plots the aggregate housing price growth rates in recourse and non-recourse states. Panel A shows the housing price growth rate per square foot over recourse law from ZIP code-level data from 1998-2012. Panel B shows the median price-to-rent growth rate from 2006-2011. Housing Price Growth (Sq. Ft) is the annual growth rate of the median of estimated home value scaled by a homes square footage of a home. Price-to-Rent growth rate is the county-level median rent value divided by county-level median housing price from the American Community Survey Census data.

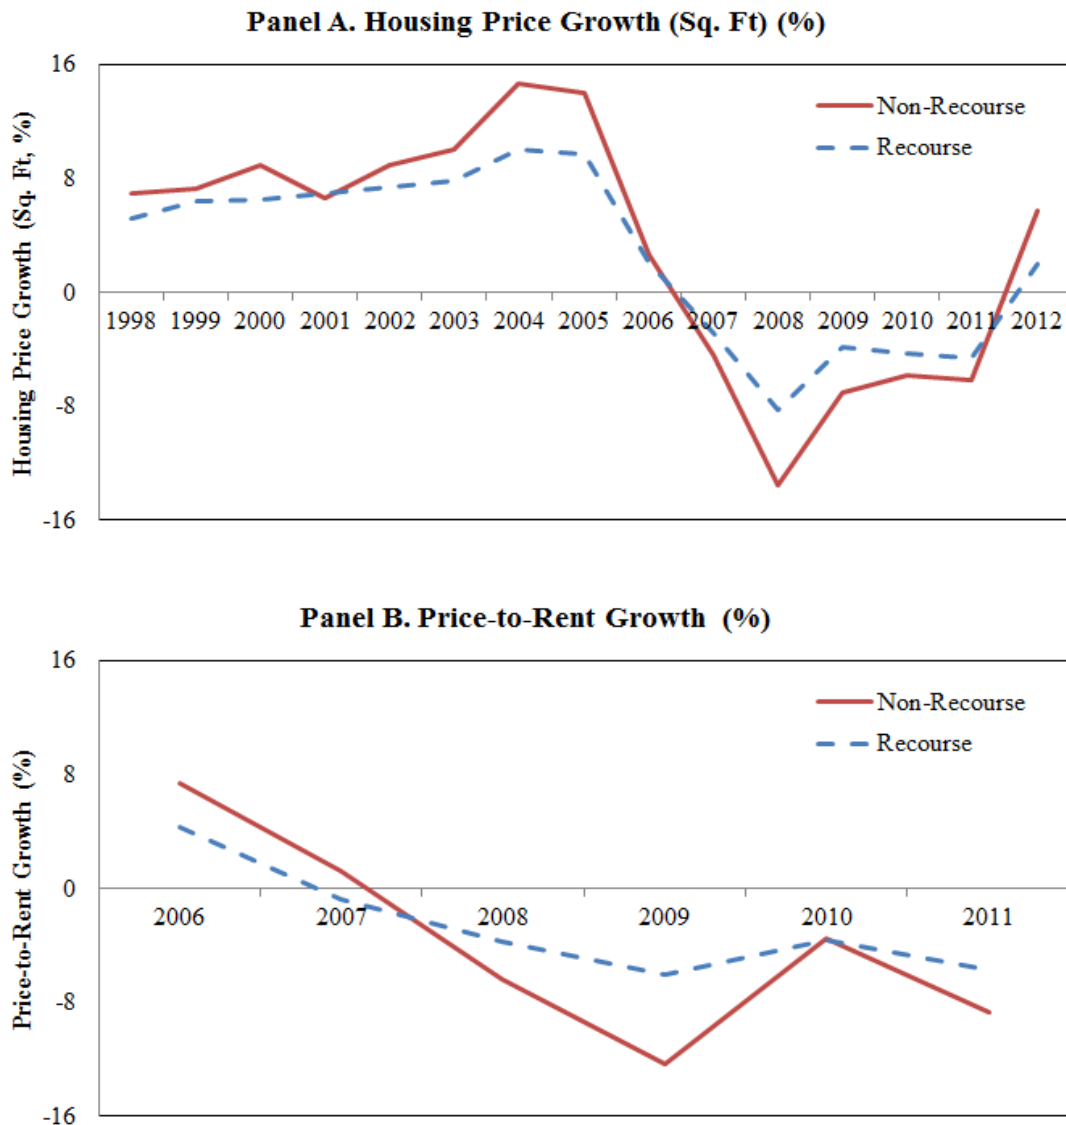

Table 1: Summary Statistics

This table presents summary statistics for the main variables used in the analysis for the period 2004-2009. The variables are defined in Appendix A.

	Mean	SD	10th	Median	90th	count
Non-recourse	0.220	0.418	0.000	0.000	1.000	50

Table 2: Univariate Analysis

This table presents the comparisons of the main variables between recourse state and non-recourse states. Panel A presents the statistics for the sample period 2004-2006 (Expansion). Panel B presents the statistics for the sample period 2007-2009 (Recession). A state is classified as a *Non-recourse* state if the state does not allow lenders to claim deficiency judgments in the event of mortgage default. The variables are defined in Appendix A. We report the differences in average value in non-recourse states and in recourse states. \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

	Non-recourse			Recourse			Diff. Mean

Table 3: Non-recourse Law and Housing Price Growth

This table reports estimates and standard errors for regressions of housing price growth on non-recourse law indicators for the sample period 2004-2009. The dependent variable in Model (1) is Housing Price Growth (Sq. Ft), the annual growth rate of the median of home value scaled by the square footage of a home using Zillow Research. Price/Rent growth rate is the annual growth rate of the county-level median rent value divided by the county-level median housing price from the American Community Survey data. HPI growth (FHFA) is the annual growth rate of the housing price index from FHFA data. The dependent variables in Models (4)-(7) are the annual growth rate of housing price growth (Sq. Ft) from Zillow Research for a certain number of bedrooms. *Recession* is a dummy variable that equals zero before and including 2006, and one after that year. A state is classified as a *Non-recourse* state if the state does not allow lenders to claim deficiency judgments in the event of mortgage default. The variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

	(1) HP growth	(2) Price/Rent growth	(3) HPI growth (FHFA)	(4) 1-Bed	(5) 2-Bed	(6) 3-Bed	(7) 4-Bed

Table 4: Non-recourse Law and Housing Price Growth: State Border Test

This table reports estimates and standard errors for regressions of housing price growth on non-recourse law indicators for the contiguous border county-pair sample in the pre-crisis period 2004-2006. The dependent variable in Model (1) is Housing Price Growth (Sq. Ft), the annual growth rate of the median of home value scaled by the square footage of a home aggregated at the ZIP code-level. The dependent variables in Models (2)-(5) are Housing Price Growth (Sq. Ft) for 1-bed, 2-bed, 3-bed and 4-bedrooms. A state is classified as a *Non-recourse* state if the state does not allow lenders to claim deficiency judgments in the event of mortgage default. *Recession* is a dummy variable that equals zero before and including 2006, and one after that year. The variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Table 5: Non-recourse Law and Housing Price Growth: Robustness Tests

This table reports estimates and standard errors for regressions of housing price growth on non-recourse law indicators with various control variables for the sample period 2004-2009. The dependent variable in Models (1)-(5) is Housing Price Growth (Sq. Ft), the annual growth rate of the median of home value scaled by the square footage of a home using Zillow Research. *Recession* is a dummy variable that equals zero before and including 2006, and one after that year. A state is classified as a *Non-recourse* state if the state does not allow lenders to claim deficiency judgments in the event of mortgage default. *Homestead exemption* is the state-specified households' home equity exemption amount in case of personal bankruptcy by homestead state laws. *Foreclosure timeline* is the state-level foreclosure time lines to complete an uncontested foreclosure. *HOEPA index* is the state-level index for anti-predatory lending laws during 2004-2005, capturing the extents of coverage, restrictions and enforcement of Home Ownership and Equity Protection Act from Bostic et al. (2008). *Housing supply* is the MSA-level housing supply elasticity provided by Glaeser et al. (2008). *HHI Bank* is the Herfindahl Hirschman Index for banking competition based on total deposit. Other economic- and demographic- controls are unreported due to the limited space. All other variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Table 6: Non-recourse Law and Housing Price Growth: Robustness Tests

This table reports estimates and standard errors for regressions of housing price growth on non-recourse law indicators with various control variables for the sample period 2004-2009. The dependent variable in Models (1)-(9) is Housing Price Growth (Sq. Ft), the annual growth rate of the median of home value scaled by the square footage of a home using Zillow Research. *Recession* is a dummy variable that equals zero before and including 2006, and one after that year. A state is classified as a *Non-recourse* state if the state does not allow lenders to claim deficiency judgments in the event of mortgage default. *Fin Literacy1-3* are the state-level financial literacy indices related to compound interest, inflation, and stock risk, respectively. *Immigrant 2000* is the proportion of immigrants for each state in 2000. *Immigrant increase* is the growth rate of immigrant between 2000 and 2014. *Immigrant Asian* is the proportion of Asian immigrants for each state in 2014. *Red states* is a dummy variable that equals one if the state predominantly vote for the Republican Party in 2004. *Industry composition* is the average GDP share of manufacturing sector in each state during 2005-2007. Other economic- and demographic- controls are unreported due to the limited space. All other variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Table 7: Non-recourse Law and Housing Speculation: Investment-purpose

This table reports estimates and standard errors for regressions of housing price growth on non-recourse law indicators and investment-purpose in the pre-crisis period 2004-2006. The dependent variable in Model (1) is Housing Price Growth (Sq. Ft), the annual growth rate of the median of home value scaled by the square footage of a home aggregated at the ZIP code-level. The dependent variables in Models (2)-(5) are Housing Price Growth (Sq. Ft) for 1-bed, 2-bed, 3-bed and 4-bedrooms. A state is classified as a *Non-recourse* state if the state does not allow lenders to claim deficiency judgments in the event of mortgage default. *High Invest* is the dummy that is one if the proportion of non-residential purpose transactions is greater than the sample median, and zero otherwise. All other variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Table 8: Non-recourse Law and Household Leverage Decision

This table reports estimates and standard errors for regressions of household investment behaviors for the sample period from 2004-2009. The dependent variable is the average debt-to-income ratio (DTI) at the ZIP code-level, defined as the total mortgage amount divided by borrower's annual income at origination date. DTI ratio for the entire mortgage loans are used in models (1)-(2), and only prime loans are used in models (3)-(4), respectively. A state is classified as a *Non-recourse* state if the state does not allow lender to claim deficiency judgments in the event of mortgage default. All other variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Table 9: Non-recourse Law and Subprime Loan Ratio

This table reports estimates and standard errors for regressions of housing price growth on the interaction term of non-recourse law indicators and *Subprime* loan ratio for the pre-crisis period. The subprime loan ratio is the aggregate ratio of the number of subprime mortgage loans to the total number of mortgage loans originated at the ZIP code-level. A state is classified as a *Non-recourse* state if the state does not allow lender to claim deficiency judgments in the event of mortgage default. All other variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Table 10: Non-recourse Law and Subprime Loan Ratio: Denial Rate

This table reports estimates and standard errors for regressions of mortgage denial rate on the interaction term of non-recourse law indicators and Subprime loan ratio.  $Denial Rate_{it}$  is the average denial rate in ZIP code-level. We estimate the fraction of loan applications denied for high risk of insolvency. The sample period is 2004-2009 in models (1) and (3). In models (2) and (4), the sample period is the pre-crisis period, 2004-2006. The subprime loan ratio is the aggregate ratio of the number of subprime mortgage loans to the total number of mortgage loans originated at the ZIP code-level. A state is classified as a *Non-recourse* state if the state does not allow lender to claim deficiency judgments in the event of mortgage default. All other variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Table 11: Interaction of Non-recourse Law and GSE Loan Ratio

This table reports estimates and standard errors for regressions of housing price growth on the interaction term of non-recourse law indicators and securitized loan ratio for the pre-crisis period, 2004-2006. The *NonGSEandGSE* loan ratio are the aggregate ratio of the number of NonGSE and GSE mortgage loans to the total number of mortgage loans originated at the county-level, respectively. The *Securitization* is the aggregate ratio of the sum of GSE and NonGSE loans to the total number of mortgage loans originated at the county-level. A state is classified as a *Non-recourse* state if the state does not allow lender to claim deficiency judgments in the event of mortgage default. All other variables are defined in Appendix A. All standard errors are robust to heteroskedasticity and clustered at the county-year level. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

	Housing Price growth (Zillow)		
	(1)	(2)	(3)

Table 12: Non-Recourse Law and Real Effect on Consumption: Descriptive Analysis

This table presents the comparisons of the per capita personal consumptions for non-durable goods between recourse state and non-recourse states for the pre-crisis period, 2004-2006. A state is classified as a *Non-recourse* state if the state does not allow lender to claim deficiency judgments in the event of mortgage default. *High Age* and *Low Age*, *High Income* and *Low Income* are defined by the sample median of household age and income from American Community Survey. We report the differences in average value in non-recourse states and in recourse states. \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

Expansion (2004-2006)	Non-Recourse			Recourse			Diff. Mean
	Mean	Median	SD	Mean	Median	SD	
Pooled Sample	0.062	0.063	0.014	0.059	0.058	0.017	0.003
High Age	0.066	0.070	0.010	0.057	0.056	0.015	0.009**
Low Age	0.059	0.059	0.017	0.062	0.060	0.018	-0.003
High Income	0.053	0.056	0.014	0.058	0.057	0.013	-0.005
Low Income	0.069	0.071	0.011	0.061	0.059	0.020	0.008*
Observations	33			117			

Table 13: Non-Recourse Law and Real Effect on Consumption

This table reports estimates and standard errors for regressions of consumption per capita on non-recourse law in state-level for the pre-crisis period, 2004-2006. The dependent variable is per capita personal consumption expenditures for non-durable goods by state from Bureau of economic analysis. A state is classified as a *Non-recourse* state if the state does not allow lender to claim deficiency judgments in the event of mortgage default. *High Age* and *Low Age*, *High Income* and *Low Income* are defined by the sample median of household age and income from American Community Survey. The independent variables include the annual growth in state-level GDP, annual growth in population and Judicial mortgage law indicator. The other variables are defined in Table 1. All standard errors are robust to heteroskedasticity. Coefficients marked \*\*\*, \*\* and \* are significant at the 1%, 5% and 10% level, respectively.

	(1) Pooled Sample	(2) High Age	(3) Low Age	(4) High Income	(5) Low Income
Non-recourse	0.001 (0.003)	0.007** (0.003)	-0.004 (0.005)	-0.005 (0.004)	0.008** (0.003)
GDP growth	0.277*** (0.096)	0.474*** (0.064)	0.151 (0.133)	0.109 (0.083)	0.314** (0.127)
